Atherosclerotic lesions are asymmetric focal thickenings of the intima of arteries that consist of lipids, various cell types and extracellular matrix (ECM). These lesions lead to vascular occlusion representing the most common cause of death in the Western world. The main cause of vascular occlusion is rupture of atheromatous lesions followed by thrombus formation. Fibronectin (FN) is one of the earliest ECM proteins deposited at atherosclerosis-prone sites and was suggested to promote atherosclerotic lesion formation. Here, we report that atherosclerosis-prone apolipoprotein E-null mice lacking hepatocyte-derived plasma FN (pFN) fed with a pro-atherogenic diet display dramatically reduced FN depositions at atherosclerosis-prone areas, which results in significantly smaller and fewer atherosclerotic plaques. However, the atherosclerotic lesions from pFN-deficient mice lacked vascular smooth muscle cells and failed to develop a fibrous cap. Thus, our results demonstrate that while FN worsens the course of atherosclerosis by increasing the atherogenic plaque area, it promotes the formation of the protective fibrous cap, which in humans prevents plaques rupture and vascular occlusion.

INTRODUCTION

Atherosclerosis is a progressive inflammatory disease of large arteries characterized by an accumulation of lipids and extracellular matrix (ECM) proteins in the affected vessel wall (Lusis, 2000). Atherosclerosis commences with the deposition of lipoprotein particles into the subendothelial matrix and the recruitment of monocytes to the luminal surface of the endothelium. Next, monocytes transmigrate across the endothelial monolayer into the intima, where they proliferate and differentiate into macrophages that take up the lipoprotein particles and form foam cells (Woollard & Geissmann, 2010). Finally, macrophage-derived chemoattractants induce the migration of vascular smooth muscle cells (vSMC) from the vessel wall into the lesion, where they secrete ECM proteins resulting in lesion growth and the formation of the ‘fibrous cap’ that encloses the lipid-rich core (Newby & Zaltsman, 1999). The rupture of fibrous caps represents an injured vessel surface and triggers adhesion and activation of platelets, which can culminate in thrombus formation and eventually myocardial infarction or stroke (Lusis, 2000). Therefore, the rupture of an atherosclerotic plaque always represents a life-threatening event. Plaque rupture depends on many factors including the composition and vulnerability of plaques (Lusis, 2000). Vulnerable plaques have thin fibrous caps and contain elevated numbers of inflammatory cells (Newby, 2007; Newby et al, 2009).

Despite the systemic nature of atherosclerotic risk factors, which comprise hypercholesterolemia, hyperglycemia, obesity and smoking, atherosclerotic lesions develop preferentially at vessel curvatures, branching points and bifurcations, where the blood flow is highly turbulent (Hahn & Schwartz, 2009). In vitro studies suggested that the turbulent blood flow at these atherosclerotic-prone sites exerts mechanical forces on endothelial cells (EC) leading to the activation of EC integrins, the secretion and deposition of fibronectin (FN) (Feaver et al., 2010) and the activation of inflammatory mediators such as NF-κB, the c-Jun NH2-terminal kinases (JNKs) and p21-activated kinase (PAK) (Funk et al., 2010; Hahn & Schwartz, 2008; Hahn et al., 2009; Orr et al., 2005, 2007, 2008). These mediators induce endothelial permeability, sustain an inflammatory state and thereby enforce the consequences of the turbulent blood flow during atherogenesis (Hahn et al., 2009; Orr et al., 2005, 2007).

FNs are a family of large ECM proteins that are generated by alternative splicing from a single gene. FN is found in all vertebrates where it exists in two different forms; one form is cellular FN (cFN), which contains, depending on the tissue, variable proportions of the alternatively spliced exons coding for the extra domains A and B (EDA, EDB). cFN is synthesized and secreted by many cells and assembled into an insoluble fibrillar matrix. The other form is plasma FN (pFN), which lacks EDA and EDB. pFN is synthesized by hepatocytes and released into the circulation where it remains soluble (Leiss et al., 2008; White et al., 2009). Assembly of FN into insoluble and biologically active fibrils critically depends on the interaction with integrins resulting in the unmasking of cryptic FN binding sites, association with other FN proteins and finally crosslinking by tissue transglutaminases into a fibrillar matrix (Hynes, 2002; Leiss et al., 2008). Soluble pFN can also be assembled into fibrils, however, only after it is bound by integrins, e.g. on platelets or after transfer into tissues (Moretti et al., 2007; Oh et al., 1981). Studies published more than 20 years ago showed that the expression of FN is elevated in vessel walls of atherosclerotic regions and, therefore, suggested a role for FN during the course of atherosclerosis (Glukhova et al., 1989). Deletion of the FN gene in mice leads to early embryonic lethality (George et al., 1993), which precludes the analysis of atherosclerosis. However, a specific ablation of the exon encoding the alternatively spliced EDA domain in atherosclerosis-prone mice was reported to reduce the number and size of atherosclerotic lesions, suggesting that the EDA domain in cFN supports atherogenesis (Babaev et al., 2008; Tan et al., 2004). In line with this observation, the expression of FN-EDA is high during atherosclerosis (Astolf & Hynes, 2009). A correlation between elevated pFN levels and increased incidence for atherosclerosis in human patients (Orem et al., 2003; Ozcelik et al., 2009; Tzanatos et al., 2009; Vavalle et al., 2007; Zhang et al., 2006). To determine whether pFN plays a role during the course of the disease, we manipulated pFN expression in atherosclerosis-prone ApoE<sup>−/−</sup> mice using the Cre-loxP system. ApoE<sup>−/−</sup> mice subjected to a high-fat diet develop atherosclerotic lesions over the course of their lifespan (Nakashima et al., 1994). To first test whether FN accumulates at sites of disturbed blood flow in our model system, we induced atherosclerosis in 3-week-old ApoE<sup>−/−</sup> mice by feeding them for 12 weeks with a high-fat diet. Oil Red O staining of aortas and the vessels branching from the aortic arch (the innominate, the left common carotid and the left subclavian arteries) confirmed the formation of large, lipid-rich plaques at areas of disturbed blood flow in the innominate and subclavian arteries, and the lesser curvature of the aortic arch (Fig 1A). The Oil Red O-positive plaques were absent before subjecting ApoE<sup>−/−</sup> mice to the high-fat diet (Fig 1A). Furthermore, cross-sections revealed FN deposits in atherosclerosis-prone regions of aortic arches and innominate arteries, while cross-sections of regions of the aorta and the carotids protected from atherosclerosis did not show FN accumulations (Fig 1B).

**Mx-Cre-mediated FN gene deletion reduced atherosclerotic plaque formation in vivo**

Since FN deposits are particularly prominent in the subendothelial space and at the luminal surface of atherosclerosis-prone regions (Fig 1B), we hypothesized that soluble pFN is deposited at these sites and thus might play an important role in atherosclerosis. To test this hypothesis, we intercrossed ApoE<sup>−/−</sup> mice carrying a loxP-flanked FN gene (ApoE<sup>−/−</sup>FN<sup>fl/fl</sup>) with mice expressing the Cre recombinase under the control of the interferon- and polyinosinic-polycytidylic acid (poly-IC)-inducible Mx promoter (Mx-Cre) to produce ApoE<sup>−/−</sup>FN<sup>MxCre</sup> mice. Deletion of the FN gene was induced in 2-week-old ApoE<sup>−/−</sup>FN<sup>MxCre</sup> mice by a single intraperitoneal injection of poly-IC. Western blot (WB) analysis confirmed loss of pFN 1 week after the poly-IC injection (Fig 2A). Elimination of pFN was stable for at least 6 months. WB analysis of cell lysates from ApoE<sup>−/−</sup>FN<sup>MxCre</sup> mice showed loss of FN expression in haematopoietic cells but neither in ECs nor in vSMCs from the aorta (Fig 2A and Supporting Information Fig 1A). Together, these results show that Mx-Cre-mediated deletion of the FN gene reduced FN deposits in the subendothelial space of atherosclerosis-prone regions and diminished the number and size of atherosclerotic lesions. Importantly, it also blocked the invasion of vSMCs and the formation of fibrous caps. Thus, pFN plays a dichotomous role in atherosclerosis: it promotes disease by supporting initiation and progression of atherosclerotic lesions but may prevent potential thrombotic events by promoting fibrous cap formation.

**RESULTS**

**FN is deposited at atherosclerosis-prone sites**

There are conflicting observations on a correlation of elevated pFN levels with an increased incidence for atherosclerosis in human patients (Orem et al., 2003; Ozcelik et al., 2009; Tzanatos et al., 2009; Vavalle et al., 2007; Zhang et al., 2006). To determine whether pFN plays a role during the course of the disease, we manipulated pFN expression in atherosclerosis-prone ApoE<sup>−/−</sup> mice using the Cre-loxP system. ApoE<sup>−/−</sup> mice subjected to a high-fat diet develop atherosclerotic lesions over the course of their lifespan (Nakashima et al., 1994). To first test whether FN accumulates at sites of disturbed blood flow in our model system, we induced atherosclerosis in 3-week-old ApoE<sup>−/−</sup> mice by feeding them for 12 weeks with a high-fat diet. Oil Red O staining of aortas and the vessels branching from the aortic arch (the innominate, the left common carotid and the left subclavian arteries) confirmed the formation of large, lipid-rich plaques at areas of disturbed blood flow in the innominate and subclavian arteries, and the lesser curvature of the aortic arch (Fig 1A).
was efficient in hepatocytes and haematopoietic cells resulting in a complete and stable elimination of pFN in ApoE<sup>−/−</sup>FN<sub>MXCre</sub> mice.

To test whether loss of pFN affects development and/or progression of atherosclerosis, we subjected ApoE<sup>−/−</sup>FN<sub>MXCre</sub> and their control (ApoE<sup>−/−</sup>FN<sub>DL/</sub>) littermates to high-fat diet and performed whole-mount staining of longitudinally opened aortas with Oil Red O to visualize the lipid-rich atherosclerotic plaques. To avoid possible confounding effects of gender differences (Goldburt & Neufeld, 1986), all experiments were performed with males. After 1 week of high-fat diet, none of the test groups displayed signs of atherosclerotic plaque formation. After 12 weeks of high fat diet, all mice developed atherosclerotic lesions with highest incidence at aortic arches and in the abdominal regions of the aorta (Fig 2B and Supporting Information Fig 1B). However, ApoE<sup>−/−</sup>FN<sub>MXCre</sub> mice showed significantly fewer atherosclerotic lesions when compared to ApoE<sup>−/−</sup>FN<sub>DL/</sub> control littermates (Fig 2B–E). Quantitative analysis of Oil Red O-stained whole mount aortas revealed that ApoE<sup>−/−</sup>FN<sub>MXCre</sub> aortas displayed a 50% reduction of lesion areas (Fig 2C), which was due to significantly fewer (Fig 2D) as well as smaller lesions (Fig 2E). Altogether, these results indicate that Mx-Cre-mediated deletion of the FN gene protects against atherosclerosis.

**Vav-Cre-mediated FN gene deletion in haematopoietic cells does not affect atherosclerosis**

The Mx-Cre transgene is known to efficiently disrupt floxed genes in hepatocytes and haematopoietic cells. To determine whether ablation of the FN gene in haematopoietic cells including monocytes/macrophages affects the course of atherosclerosis, we intercrossed ApoE<sup>−/−</sup>FN<sub>DL/</sub> mice with mice expressing the Cre recombinase under the control of the Vav promoter (Vav-Cre) to generate ApoE<sup>−/−</sup>FN<sub>VavCre</sub> mice. WB analysis of cell lysates from ApoE<sup>−/−</sup>FN<sub>VavCre</sub> mice showed loss of FN expression in haematopoietic cells but neither in hepatocytes nor in ECs and vSMCs from aorta (Fig 3A and unpublished observation). Consistent with normal FN gene activity in hepatocytes, ApoE<sup>−/−</sup>FN<sub>VavCre</sub> mice showed similar pFN levels as ApoE<sup>−/−</sup>FN<sub>DL/</sub> control littermates (Fig 3A and Supporting Information Fig 1C).

Similar to ApoE<sup>−/−</sup>FN<sub>DL/</sub> and ApoE<sup>−/−</sup>FN<sub>MXCre</sub> mice, ApoE<sup>−/−</sup>FN<sub>VavCre</sub> mice did not develop atherosclerotic lesions after 1 week of high-fat diet. However, after 12 weeks of a high-fat diet, ApoE<sup>−/−</sup>FN<sub>VavCre</sub> mice showed atherosclerotic plaques at atherosclerosis-prone regions (Fig 3B). The overall areas covered with lesions as well as the atherosclerotic plaque sizes and numbers did not differ from those observed in ApoE<sup>−/−</sup>FN<sub>DL/</sub> control littermates (Fig 3C–E). These findings indicate that FN derived from haematopoietic cells does not exert a major impact on the development of atherosclerosis.

**Loss of pFN reduced FN deposition at atherosclerosis-prone areas**

Lack of pFN significantly reduced the size and number of atherosclerotic lesions. It has been postulated and confirmed in this study (Fig 1B) that FN is deposited at atherosclerosis-prone areas before lesions become visible (Hahn et al., 2009; Orr et al., 2005). To this end, we treated ApoE<sup>−/−</sup>FN<sub>DL/</sub>, ApoE<sup>−/−</sup>FN<sub>VavCre</sub> and ApoE<sup>−/−</sup>FN<sub>MXCre</sub> mice for 1 week with a high-fat diet and subsequently compared the extent of FN deposits in cross-sections of the atherosclerosis-prone lesser curvature of aortic arches.

Neither mouse strain showed evidence of atherosclerotic plaques after 1 week of high-fat diet. ApoE<sup>−/−</sup>FN<sub>DL/</sub> and ApoE<sup>−/−</sup>FN<sub>VavCre</sub> mice showed continuous FN deposits at atherosclerosis-prone areas (Fig 4A). In contrast, ApoE<sup>−/−</sup>FN<sub>MXCre</sub> mice displayed significantly less and often...
discontinuous FN staining at the corresponding sites (Fig 4A). These results indicate that pFN, but not haematopoietic cell-derived FN, is deposited at atherosclerosis-prone sites prior to the development of atherosclerotic lesions.

Obesity and hypercholesterolemia are major risk factors for developing atherosclerosis (Lusis, 2000). Since hepatocytes play an important role in cholesterol homeostasis and FN is deleted in these cells, we determined total cholesterol, high-density lipoprotein (HDL) cholesterol and glucose levels and body weight in ApoE\textsuperscript{+/+}/C0\textsuperscript{+/+}/C0\textsuperscript{+/+}FNfl/fl and ApoE\textsuperscript{+/+}/C0\textsuperscript{+/+}/C0\textsuperscript{+/+}FNMxCre mice treated for 12 weeks with a high-fat diet. We found no differences in either cholesterol, HDL (Fig 4B) and glucose levels (Fig 4C) or in body weight (Fig 4D) between ApoE\textsuperscript{+/+}/C0\textsuperscript{+/+}/C0\textsuperscript{+/+}FNfl/fl and ApoE\textsuperscript{+/+}/C0\textsuperscript{+/+}/C0\textsuperscript{+/+}FNMxCre mice. These results exclude an involvement of risk factors in the differential development of atherosclerosis in ApoE\textsuperscript{+/+}/C0\textsuperscript{+/+}/C0\textsuperscript{+/+}FNfl/fl and ApoE\textsuperscript{+/+}/C0\textsuperscript{+/+}/C0\textsuperscript{+/+}FNMxCre mice.

Expression of inflammatory mediators and recruitment of monocytes are reduced in ApoE\textsuperscript{+/+}/FNMxCre mice

Integrin-FN interactions are believed to promote monocyte/macrophage recruitment and to maintain an inflammatory milieu at atherosclerosis-prone sites by sustaining shear stress-induced NF-κB and PAK activation in ECs, which in turn leads to the expression of downstream genes such as ICAM-1 (Orr et al, 2007) or the activation of signalling molecules such as JNK (Hahn et al, 2009). To analyze whether pFN modulates NF-κB, PAK and JNK activity in vivo, we compared the levels of the phosphorylated NF-κB subunit p65, phospho-PAK, phospho-JNK and ICAM-1 on cross-sections of the atherosclerosis-prone lesser curvatures of aortic arches from ApoE\textsuperscript{+/+}/C0\textsuperscript{+/+}/C0\textsuperscript{+/+}FNfl/fl and ApoE\textsuperscript{+/+}/C0\textsuperscript{+/+}/C0\textsuperscript{+/+}FNMxCre mice fed for 1 week with a high-fat diet. ApoE\textsuperscript{+/+}/C0\textsuperscript{+/+}/C0\textsuperscript{+/+}FNfl/fl mice had abundant phospho-NF-κB/p65, phospho-PAK, phospho-JNK and ICAM-1 on the luminal surface of the ECs (Fig 5A). In contrast, ApoE\textsuperscript{+/+}/FNMxCre mice displayed lower levels of phospho-NF-κBp65, phospho-PAK, phospho-JNK and ICAM-1 in corresponding areas (Fig 5A). Interestingly, atherosclerotic plaques of ApoE\textsuperscript{+/+}/C0\textsuperscript{+/+}/C0\textsuperscript{+/+}FNfl/fl and ApoE\textsuperscript{+/+}/FNMxCre mice fed for 10 weeks with a high-fat diet showed similar expression of all tested inflammatory markers (Supporting Information Fig 2A). These results indicate that depositions of pFN facilitate activation of inflammatory mediators at atherosclerosis-prone sites in vivo.
To further confirm these results, we cultured ECs in the presence and absence of pFN and monitored the expression of ICAM-1 by WB. In line with our in vivo results, ICAM-1 levels were reduced in ECs when they were cultured in the absence of pFN (Fig 5B).

Adhesion of monocytes to the endothelium is required for the initiation of atherosclerosis (Woollard & Geissmann, 2010). To analyze whether pFN depositions modulate adhesion of monocytes to ECs, we analyzed leukocyte adhesion on the endothelium in atherosclerosis-prone regions of the carotid artery of ApoE\(^{-/-}\)FNfl/fl and ApoE\(^{-/-}\)FNMxCre mice using intravital microscopy and found that the number of adherent leukocytes was reduced in ApoE\(^{-/-}\)FNMxCre mice when compared to ApoE\(^{-/-}\)FNfl/fl control littermates (Fig 5C and D). Since the number of circulating leukocytes is influencing their adhesion to the endothelium, we determined their numbers and found that they were similar in ApoE\(^{-/-}\)FNfl/fl and ApoE\(^{-/-}\)FNMxCre mice (unpublished observation). The adhesion of leukocytes to the endothelium is mediated by the interaction of \(\alpha_4\beta_1\) integrins with VCAM-1 (Barringhaus et al, 2004). Immunostaining of cross-sections of aortic arches with anti-VCAM-1 antibodies and FACS analyses of leukocytes to quantify \(\alpha_4\beta_1\) integrin surface levels revealed normal levels of both adhesion molecules in ApoE\(^{-/-}\)FNfl/fl and ApoE\(^{-/-}\)FNMxCre mice fed for 1 week with a high-fat diet (Supporting Information Fig 2B and 2C).

Next, we measured cell adhesion of Mac-1-positive cells to monolayers of ECs under static and laminar flow conditions, both in the presence and absence of pFN. We used bEnd5 endothelioma cells to test adhesion, since they were shown to promote adhesion of haematopoietic cells equally well as primary ECs (Steiner et al, 2010). Mac-1-positive cells cultured in absence of pFN were suspended in pFN-free medium or pFN-complemented medium (10 mg/ml) and then seeded onto a bEnd5 monolayer. Quantification of adherent cells revealed that twofold more Mac-1-positive cells adhered to the bEnd5 monolayer when they were cultured in pFN-complemented medium as compared to pFN-free medium (Fig 5E), indicating that soluble pFN promotes adhesion of Mac-1-positive cells to ECs.

During atherosclerosis, low-density lipoprotein (LDL) particles aggregate and become oxidized in the vascular ECM. Oxidized LDL will be taken up by macrophages resulting in the formation of foam cells. To quantify the relative size of single lesions, values were mean ± SD; \(p = 0.27, 0.08, 0.41\) and 0.055; n.s. = not significant.
Figure 4. Reduced FN depositions in the aortic arch of ApoE<sup>−/−</sup> FN<sup>MxCre</sup> mice.

A. Immunostaining of FN in the lesser curvature of the aortic arch from ApoE<sup>−/−</sup> FN<sup>MxCre</sup>, ApoE<sup>−/−</sup> FN<sup>YavCre</sup> mice and their respective ApoE<sup>−/−</sup> FN<sup>fl/fl</sup> mice. Arrowheads point to FN signals at the luminal side of the arch. Nuclei are visualized with DAPI. Scale bar represents 75 μm in all images.

B. Fasting cholesterol and HDL cholesterol levels of ApoE<sup>−/−</sup> FN<sup>fl/fl</sup> (n = 13) and ApoE<sup>−/−</sup> FN<sup>MxCre</sup> (n = 13) mice after 12 weeks on a high-fat diet. Values are mean ± SD; p = 0.33. n.s. = not significant.

C. Fasting glucose levels of ApoE<sup>−/−</sup> FN<sup>fl/fl</sup> (n = 13) and ApoE<sup>−/−</sup> FN<sup>MxCre</sup> (n = 13) mice after 12 weeks on a high-fat diet. Values are mean ± SD; p = 0.15. n.s. = not significant.

D. Body weight of ApoE<sup>−/−</sup> FN<sup>fl/fl</sup> (n = 28) and ApoE<sup>−/−</sup> FN<sup>MxCre</sup> (n = 16) mice after 12 weeks on a high-fat diet. Values are mean ± SD; p = 0.11. n.s. = not significant.
formation of aggregated and oxidized LDL foam cells (Woollard & Geissmann, 2010). To test whether pFN modulates lipid accumulation in plaques, we stained cross-sections of atherosclerotic plaques from ApoE−/−FNfl/fl and ApoE−/−FNxCre mice with Oil Red O. Lipids were detected in the core region of the plaques and a similar lipid accumulation was found in ApoE−/−FNfl/fl and ApoE−/−FNxCre mice (Fig 6A). To determine whether FN affects macrophage uptake of modified LDL, we incubated freshly isolated macrophages from ApoE−/−FNfl/fl and ApoE−/−FNxCre mice after incubating them for 4 and 24 h with acLDL and found that also the acLDL uptake was normal (Fig 6C). Collectively, these results indicate that FN is dispensable for foam cell formation.

Atherosclerotic lesions in ApoE−/−FNxCre mice lack the fibrous cap

Advanced atherosclerotic lesions are characterized by a subendothelial accumulation of vSMCs, which synthesize and deposit a collagen- and FN-rich matrix into the fibrous cap (Newby & Zaltsman, 1999). To test whether loss of pFN alters fibrous cap formation, we immunostained cross-sections of similarly sized atherosclerotic plaques from ApoE−/−FNfl/fl and ApoE−/−FNxCre mice for Mac-1 to visualize monocyte/
macrophages, Thy-1.2/CD3 to visualize T cells, alpha-smooth muscle actin (αSMA) to visualize vSMCs and the ECM proteins FN and collagen type I (Col-I). After 12 weeks of high-fat diet, atherosclerotic plaques from ApoE<sup>−/−</sup>FN<sup>fl/fl</sup> mice consisted of macrophage-derived foam cells that were covered at the luminal side with a FN- and collagen-rich matrix and a continuous layer of vSMCs (Fig 7A and B and Supporting Information Fig 4A). A few T cells were detected, mainly at the edges of a few plaques (Supporting Information Fig 4B). In sharp contrast, atherosclerotic plaques from ApoE<sup>−/−</sup>FN<sup>MXCre</sup> mice lacked vSMCs and a collagen matrix and consisted mainly of macrophage-derived foam cells (Fig 7A and B and Supporting Information Fig 4A). Similarly, atherosclerotic plaques of ApoE<sup>−/−</sup>FN<sup>MXCre</sup> mice fed for 6 months with a high-fat diet also lacked vSMCs and a collagen matrix. Distribution and number of T cells were unaffected in ApoE<sup>−/−</sup>FN<sup>MXCre</sup> mice (Supporting Information Fig 4B).

To determine whether monocyte/macrophage-derived FN contributes to vSMCs recruitment and fibrous cap formation, we analyzed lesions from ApoE<sup>−/−</sup>FN<sup>avCre</sup> mice and found that the cellular composition of their lesions and the FN deposits in their fibrous caps were similar to ApoE<sup>−/−</sup>FN<sup>fl/fl</sup> control littermates (Supporting Information Fig 4C). Together, these results indicate that pFN plays an important role in promoting the formation of the fibrous cap.

pFN stimulates vSMC migration
Why do vSMCs fail to colonize the fibrous caps in ApoE<sup>−/−</sup>FN<sup>MXCre</sup> mice? Successful accumulation of vSMCs in atherosclerotic lesions and subsequent formation of the fibrous cap depends on a number of factors including vSMC proliferation and survival rates as well as their ability to migrate into the lesions (Newby & Zaltsman, 1999). We found no apparent defects in vSMCs proliferation nor did we observe increased apoptosis in lesions from ApoE<sup>−/−</sup>FN<sup>MXCre</sup> mice subjected to high-fat diet. To test whether pFN modulates migration of vSMCs, we isolated primary vSMCs and performed chemotaxis assays using transwell motility chambers using pFN as a

Figure 6. Normal foam cell formation in ApoE<sup>−/−</sup>FN<sup>MXCre</sup> mice.

A. Staining atherosclerotic plaques from ApoE<sup>−/−</sup>FN<sup>fl/fl</sup> and ApoE<sup>−/−</sup>FN<sup>MXCre</sup> mice 12 weeks after a high fat diet with Oil Red O and haematoxylin. Scale bar represents 100 μm.

B. Staining of macrophages from ApoE<sup>−/−</sup>FN<sup>fl/fl</sup> and ApoE<sup>−/−</sup>FN<sup>MXCre</sup> mice with Oil Red O and haematoxylin 24-h after incubating them with LDL or AcLDL, respectively. Scale bar represents 20 μm.

C. Quantification of acLDL uptake by macrophages from ApoE<sup>−/−</sup>FN<sup>fl/fl</sup> and ApoE<sup>−/−</sup>FN<sup>MXCre</sup> mice. Values are mean ± SD; p = 0.36 and 0.29. n.s. = not significant.
chemoattractant in the lower part of the chambers. We observed that pFN increased the migration of vSMCs in a concentration-dependent manner (Fig 7C). When we added plasma samples from ApoE^{-/-}FN^{fl/fl} and ApoE^{-/-}FN^{Cre} mice to the lower part of the migration chamber, we found that plasma from ApoE^{-/-}FN^{fl/fl} mice induced twofold higher migration rates of vSMCs than plasma from ApoE^{-/-}FN^{Cre} mice (Fig 7D). Importantly, the decreased migration rates of vSMCs towards plasma derived from ApoE^{-/-}FN^{Cre} mice could be rescued by supplementing the plasma with FN (Fig 7D). These results clearly indicate that pFN is a motility factor for vSMCs.

**DISCUSSION**

FN deposits and atherosclerotic lesions preferentially form at sites of disturbed blood flow (Hahn & Schwartz, 2009). *In vitro* studies with shear-stressed ECs cultured on FN suggest that the FN deposits enforce and maintain a pro-atherogenic milieu through integrin binding and signalling (Feaver et al, 2010). It is not known, however, whether FN serves a similar function *in vivo* and whether the FN depositions are derived from the circulation or from infiltrating monocytes and/or resident ECs. To address these questions, we generated mice lacking the FN gene either in hepatocytes and/or haematopoietic cells and crossed them with atherosclerosis-prone ApoE-null mice and fed them a high-fat diet. Loss of FN expression in blood cells modulated neither the development nor progression of atherosclerosis in mice. In contrast, loss of pFN abrogated FN depositions at atherosclerosis-prone sites resulting in the formation of smaller and fewer atherosclerotic lesions. However, they were covered only with a thin layer of matrix proteins, which is usually a sign of fragility and increased susceptibility for ruptures in human atherosclerotic plaques. These findings suggest a dual function for pFN during atherosclerosis: it supports plaque initiation by providing an adhesive matrix for monocytes and at late stages, it protects the lesions by controlling the formation of the fibrous cap. Thus, targeting atheroma initiation and growth by modulating FN production might have the unforeseen consequences of promoting plaque rupture and arterial occlusions resulting in a significant increase in vascular morbidity and mortality.
The subendothelial matrix of the healthy vasculature is mainly composed of basement membrane (BM) components including collagen IV and laminins. During pathological situations such as inflammation, wound healing or atherosclerosis transitional matrix proteins such as FN or fibrinogen are deposited into the subendothelial matrix (Hahn & Schwartz, 2009). In atherosclerosis, FN is deposited at sites of disturbed flow before fatty streaks are formed (Hahn & Schwartz, 2009; Hahn et al, 2009; Orr et al, 2005) but the source of the FN deposits is not known. In vitro studies have shown that disturbed flow induces the expression and deposition of FN by ECs (Feaver et al, 2010) suggesting that shear-stressed ECs deposit FN into the vessel wall. We confirmed these findings showing that FN is indeed deposited into the subendothelial space at sites of disturbed blood flow. Since pFN can be transferred from the plasma into tissues (Moretti et al, 2007; Oh et al, 1981), we next tested whether pFN contributes to the FN deposits. To this end, we ablated a conditional FN-null allele in ApoE-null mice with the Mx-Cre transgene (ApoE/−/FN<sup>FNMxCre</sup>) that deletes efficiently in hepatocytes and haematopoietic cells, and fed the offspring a high fat diet. The Mx-Cre transgene can also delete genes at low efficiency in other tissues than liver and blood cells, which is, however, efficiently compensated by diffusion of FN from non-deleted neighbouring cells (Sakai et al, 2001). The ApoE/−/FN<sup>FNMxCre</sup> offspring showed very little FN at atheropane spaces suggesting that pFN represents a major source for FN deposits at the atherosclerosis-prone areas of the vasculature. The presence of residual FN in vessel walls of ApoE/−/FN<sup>FNMxCre</sup> mice indicates that small contributions from ECs and/or vSMCs may add to the FN deposits at atherosclerosis-prone areas. Previous reports associating increased pFN levels with atherosclerosis (Orem et al, 2003) and ischemic heart disease (Ozzelik et al, 2009; Song et al, 2001; Tazznatos et al, 2009) support a role of pFN as atherosclerosis promoting factor. On the other hand, however, it has also been shown that pFN levels were unchanged or even decreased in cohorts of atherosclerosis patients (Vavalle et al, 2007; Zhang et al, 2006). It is thus possible that other risk factors, which probably depend on the patient population, are able to either attenuate or aggravate the effect of pFN on the course of atherosclerosis. Unfortunately, the nature of these risk factors is not known.

In atherosclerosis, it is believed that binding of fibrillar collagens to α2β1 prevents pro-inflammatory signals, while FN sustains a shear-stressed induced inflammatory environment and therefore is thought to aggravate the course of the disease. Mechanistically, FN mediates its pro-inflammatory role through β1-containing integrins, most likely α5β1 (Orr et al, 2006), which in turn induces phosphorylation of NF-κB through the activation of the small GTPase Rac1 (Tzima et al, 2002). In line with these findings we found that ECs of ApoE/−/FN<sup>FNMxCre</sup> mice contain significantly less of the phosphorylated NF-κB subunit p65 and less phosphorylated PAK, and develop smaller plaques than control mice. In line with reduced NF-κB activity we also observed reduced expression of the downstream gene ICAM-1 on ECs. Consequently, the adhesion of monocytes to the endothelium at atherosclerosis-prone regions in ApoE/−/FN<sup>FNMxCre</sup> mice was also reduced when compared to control littermates, providing a good explanation for the reduced recruitment of monocytes to atherosclerosis-prone sites. Interestingly, we found that the levels of inflammatory markers in developed lesions of ApoE<sup>FNMxCre</sup> mice were comparable with those of control mice, indicating that pFN is required for inflammation during plaque initiation, but not anymore once the plaques have formed. Since the deletion of the FN gene in monocytes by Vav-Cre did not affect the course of atherosclerosis, we expected normal monocyte recruitment to plaques in these mice, although we did not confirm this by intravitral microscopy. In summary, we collected several lines of evidence suggesting that monocyte recruitment is indeed impaired in pFN-deficient mice: the expression of ICAM-1 on ECs was markedly reduced, the adhesion of monocytes to the endothelium was reduced in pFN-deficient mice, and the number and size of atherosclerotic plaques was significantly diminished in ApoE/−/FN<sup>FNMxCre</sup> mice.

The reduced number and size of atherosclerotic plaques in ApoE/−/FN<sup>FNMxCre</sup> mice corroborate previous observations made using in vitro systems. In addition, our findings revealed a previously unknown function for FN in atherosclerosis. Almost all atherosclerotic lesions in ApoE/−/FN<sup>FNMxCre</sup> mice were devoid of vSMC, contained reduced levels of collagen I and lacked a fibrous cap, which points to a role for FN in the reinforcement of atherosclerotic plaques. Atherosclerotic plaques that are not stabilized with fibrous caps in humans lead to an increased likelihood of rupture and subsequent thrombus-mediated vascular occlusion leading to myocardial infarction, stroke and sudden death (Lusis, 2000). Unfortunately, plaque ruptures with thrombosis do not occur in mouse models and therefore, the consequences could not be tested (Glass & Witztum, 2001; Libby et al, 2011). The formation of a fibrous cap critically depends on the activation and proliferation of vSMCs in the intima of the affected vessel and their subsequent migration into the plaque area where they deposit a collagen-rich matrix. Since we found normal proliferation and survival rates of vSMCs in ApoE/−/FN<sup>FNMxCre</sup> mice, we conclude that the vascular FN deposits represent a trigger for the recruitment of vSMCs. This notion is supported by our in vitro experiments demonstrating that vSMCs were less efficient at migrating towards plasma lacking pFN.

These new findings strongly argue against the use of inhibitors designed to treat atherosclerosis by blocking the function of FN, such as by using peptides derived from FN. This type of treatment would inhibit pro-inflammatory signalling and thus reduce the number and size of atherosclerotic plaques but would also at the same time destabilize these plaques and increase the danger of thrombus formation and thrombotic diseases. Furthermore, reducing pFN levels would also destabilize thrombi and trigger the shedding of platelet clumps into the circulation (Ni et al, 2003) resulting in chronic embolism.

### MATERIALS AND METHODS

**Animal procedures**

ApoE<sup>FNM</sup> (Jackson Laboratory) and FN<sup>FNM</sup> mice (Sakai et al, 2001) were intercrossed with Mx-Cre transgenic mice (Kuhn et al, 1995; Schneider...
et al, 2003) to produce ApoE^{−/−}FN^{+/-} mice, or with Vav-Cre transgenic mice (Georgiades et al, 2002) to produce ApoE^{−/−}FN^{+/-} mice. Deletion of the floxed FN alleles was induced in 2-week-old mice by a single intraperitoneal injection of 175 μg poly-IC (Sigma). Atherosclerosis was accelerated by feeding the mice for 12 weeks with a high fat diet (provided by Altromin, Lage/Lippe, Germany) containing 21% fat, 0.15% cholesterol but lacking cholate (composition according to Harlan Teklad TD88137 diet). All experiments with mice were performed in accordance to German guidelines and regulations.

**Atherosclerotic lesion analysis**

Mice were anesthetized with Avertin, hearts were perfused with 15 ml of phosphate-buffered saline (PBS) containing 5 mM ethylenediaminetetraacetic acid (EDTA) and then with PBS containing 2% paraformaldehyde (PFA), 7.5% sucrose. The adventitia was thoroughly cleaned of phosphate-buffered saline (PBS) containing 5 mM ethylenediaminetetraacetic acid (EDTA) and then with PBS containing 2% paraformaldehyde (PFA), 7.5% sucrose. The adventitia was thoroughly cleaned. After 5 min equilibration in 60% isopropanol, aortas were stained with Oil Red O (Sigma, Germany), plaques were analyzed under the Leica MZ16FA stereomicroscope, and quantified with Metamorph© software. The aortic lesions of each animal are presented as percentage of the total aortic luminal surface area.

**Plasma cholesterol**

Total and HDL cholesterol levels in plasma were quantified as previously described (Dunér et al, 2011; Fredrikson et al, 2003).

**Plasma glucose measurement**

Plasma glucose was measured using a commercial kit (Abcam).

**Antibodies**

The following antibodies were used: biotinylated rat anti-Mac-1 monoclonal antibody (Pharmingen), CD3-PE, Thy-1.2 CD90.2, GM-130, ICAM-1, PECAM-1 (CD31) (all from Pharmingen), Cy3-coupled mouse anti-αSMA antibody (Sigma), rabbit anti-FN polyclonal antibody (Millipore), rabbit anti-Col-I antibody (Millipore), phospho-NFκB p65 (Santa Cruz), phospho-PAK1/2 (Cell Signaling), phosphor-JNK (Cell Signaling). Secondary antibodies were purchased from Jackson Immuno Research Laboratories, Molecular Probes or Invitrogen.

**Histology and immunostaining**

Heart and aorta tissues were embedded into a cryo-matrix (Thermo) and 10 or 12 μm sections were prepared using a cryotome. Sections were blocked with 3% bovine serum albumin (BSA) 0.2% Triton-X in PBS and incubated with antibodies.

**Intravital microscopy**

Intravital microscopy of the left carotid artery was performed as described previously (Drechsler et al, 2010). The left jugular vein was cannulated with polyethylene tubing (PE50) for the intravenous administration of anti-Gr1 antibodies (RB6-8C5, 2.5 μg/mouse) for visualizing inflammatory monocytes and neutrophils and rhodamine 6G to visualize total leukocytes. Intravital microscopy was performed with an Olympus BX51 microscope equipped with a Hamamatsu 9100-02 EMCCD camera and a 10× saline-immersion objective. For image acquisition and analysis Olympus cell^® software was used.

**Isolation of smooth muscle cells**

Aortas were dissected, longitudinally opened, washed with PBS, cut and digested with digestion buffer (2 mg/ml collagenase type II and 0.5 mg/ml elastase in Dulbecco’s modified Eagle medium (DMEM)) for 30 min at 37°C. Digestion was terminated with 10% foetal bovine serum (FBS) in DMEM. Released cells were centrifuged and re-suspended in DMEM containing 10% FBS, transferred to 6-well dishes and further expanded for analysis.

**Isolation of aortic endothelial cells**

Cells were isolated as previously described (Kobayashi et al, 2005).

**In vitro foam cell formation assay**

Thiglycolate-elicited peritoneal macrophages were plated on 12-well plates in macrophage serum-free medium (Macrophage-SFM, Invitrogen). After 24 h, non-adherent cells were washed off, and macro-
phages were incubated in fresh serum-free medium supplemented with 50 μg/ml native, acetylated human LDL (acLDL) or buffer control for 24–72 h. Cells were stained for 60 min with Oil Red O and counterstained with haematoxylin.

Modified LDL uptake
Thioglycolate-elicited peritoneal macrophages were plated on coverslips in macrophage serum-free medium (Invitrogen). After 24 h, non-adherent cells were washed off and adherent macrophages were incubated in serum-free medium complemented with 10 μg/ml native, acLDL: Dil for 4 or 24 h. Afterwards cells were washed with PBS, fixed with 4% PFA and nuclei were stained with 4,6-diamidino-2-phenylindole (DAPI). Fluorescence was analyzed with ImageJ software. Five microscopic fields were counted per experiment.

SDS–PAGE and immunoblotting
Plasma samples and cells were incubated in lysis buffer (150 mM NaCl, 50 mM Tris pH 7.4, 1 mM EDTA, 1% Triton X-100 supplemented with protease inhibitors (Roche)), homogenized in Laemmli sample buffer and boiled for 5 min. Proteins were resolved by SDS–polyacrylamide gel electrophoresis (SDS–PAGE) gels and then electrophoretically transferred from the gels onto nitrocellulose membranes, which were subsequently incubation with antibodies. Bound antibodies were detected using enhanced chemiluminescence (Millipore Corporation, Billerica, USA).

Migration assay
Migration assays were performed in 8 μm pore size chamber inserts (BD Falcon). 4 × 10^4 vSMCs were seeded into the chambers, which were then transferred into 24-well plates containing serum-free medium supplemented with dilutions of pFN or plasma from control and ApoE–/– FN^Mac^e mice, respectively. After an overnight incubation, the cells in the bottom part of the chamber were fixed in 4% PFA and stained with 0.2% crystal violet. Five microscopic fields per chamber were counted. Data are represented as percentage of reference cell number/field. Three independent experiments were performed, each of them in triplicate.

Adhesion assays
Adhesion assays of primary peritoneal macrophages to the endothelial cell line bEnd5 were carried out as follows. bEnd5 cells were cultured in serum-free medium in 4-well NUNC chamber slides until confluence, either on 1 μg/ml FN or on plastic. Macrophages were isolated and co-cultured with bEnd5 cells for 6 h, either with additional FN (10 μg/ml) or without in the medium. Cells were washed with PBS, fixed with 4% PFA and stained for Mac-1. Six microscopic fields were counted per experiment. Adhesion assays of primary peritoneal macrophages under flow conditions were carried out with bEnd5 cells. bEnd5 cells were cultured in serum-free medium or serum-free medium containing 10 μg/ml FN in a μ-Slide I 0.4 μm Luer (Ibidi) over night. Primary macrophages were isolated and cultured in FN-free medium or medium containing 10 μg/ml FN. Macrophages were perfused at 2.5 dyn/cm^2 at 37°C over the endothelial monolayer for 10 min. Cells were washed with PBS, fixed with 4% PFA, stained for the Mac-1 antigen and the adherent macrophages were then counted in 10 microscopic fields per experiment.

Statistical analysis
The statistical analysis was performed using the Student’s-t-test. The values are presented as mean ± SD.

Author contributions
The study was conceived by RF. IR, KB, EM performed most experiments and analyzed them together with RF. EB, PD and JN made cholesterol measurements and OS intravital microscopy experiments. RF and EM wrote the manuscript. All authors read and approved the manuscript.

Acknowledgements
The authors thank MSc Klaus Kemmerich for excellent technical assistance. KB was supported by EMBO. The work was funded by the Deutsche Forschungsgemeinschaft (SFB-914; to OS and RF) and the Max Planck Society (to RF).
