The epidermis functions to create a barrier to protect from water loss and exclude foreign substances and microorganisms. It consists of a multi-layered stratified epithelium with viable basal, spinous, and granular layers and a dead cornified layer (stratum corneum). The epidermal barrier is maintained and continuously regenerated by terminally differentiating keratinocytes, in a highly organized process called cornification (Candi et al., 2005). After the proliferating basal keratinocytes detach from the underlying basement membrane, they are committed to terminal differentiation and form the cornified layer, which consists of flattened cell remnants (corneocytes) surrounded by insoluble lipids. These detached suprabasal keratinocytes undergo several

Epidermal ADAM17 maintains the skin barrier by regulating EGFR ligand-dependent terminal keratinocyte differentiation

Claus-Werner Franzke,1 Cristina Cobzaru,1 Antigoni Triantafyllopoulou,2 Stefanie Löffek,1 Keisuke Horiuchi,3 David W. Threadgill,4 Thomas Kurz,5 Nico van Rooijen,6 Leena Bruckner-Tuderman,1,7 and Carl P. Blobel8,9,10

ADAM17 (a disintegrin and metalloproteinase 17) is ubiquitously expressed and cleaves membrane proteins, such as epidermal growth factor receptor (EGFR) ligands, L-selectin, and TNF, from the cell surface, thus regulating responses to tissue injury and inflammation. However, little is currently known about its role in skin homeostasis. We show that mice lacking ADAM17 in keratinocytes (A17−/KC) have a normal epidermal barrier and skin architecture at birth but develop pronounced defects in epidermal barrier integrity soon after birth and develop chronic dermatitis as adults. The dysregulated expression of epidermal differentiation proteins becomes evident 2 d after birth, followed by reduced transglutaminase (TGM) activity, transepidermal water loss, up-regulation of the proinflammatory cytokine IL-36γ, and inflammatory immune cell infiltration. Activation of the EGFR was strongly reduced in A17−/KC skin, and topical treatment of A17−/KC mice with recombinant TGF-α significantly improved TGM activity and decreased skin inflammation. Finally, we show that mice lacking the EGFR in keratinocytes (Egfr−/KC) closely resembled A17−/KC mice. Collectively, these results identify a previously unappreciated critical role of the ADAM17–EGFR signaling axis in maintaining the homeostasis of the postnatal epidermal barrier and suggest that this pathway could represent a good target for treatment of epidermal barrier defects.

transcriptional and morphological changes during their translocation to the skin surface. Although these morphogenetic changes during epidermal stratification are well documented, the molecular processes of terminal differentiation, which are crucial for the development and homeostasis of the epidermal barrier, are not well understood (Blanpain and Fuchs, 2009).

The cornification process of granular keratinocytes begins with the formation of the cornified envelope (CE), an insoluble protein structure which is stabilized by trans-glutaminases (TGMs). It replaces the plasma membrane and functions as a scaffold for the attachment of insoluble lipids (Candi et al., 2005). The TGMs 1 and 3 are responsible for the characteristic resistance and insolubility of the CE because they cross-link its structural components like involucrin, loricrin, filaggrin, and the small proline-rich proteins. Specifically, the cytosolic TGM3 cross-links various CE components into small oligomers, which are then translocated and cross-linked onto the growing CE at the cell periphery by the membrane-bound TGM1 (Hitomi, 2005). A well balanced equilibrium of corneocyte differentiation and their controlled release from the skin surface (desquamation) is crucial to maintain the epidermal barrier and ensure its renewal every 3 wk (Blanpain and Fuchs, 2009).
The epidermal growth factor receptor (EGFR) is most prominently expressed in proliferating basal keratinocytes and to a lesser degree in suprabasal keratinocytes. It supports basal keratinocyte proliferation and delays apoptosis in suprabasal keratinocytes that have lost their interaction with the matrix (Pastore and Mascia, 2008; Pastore et al., 2008; Schneider et al., 2008). EGFR deficiency causes defects in hair follicle development and immature epidermal differentiation with inflammatory skin reactions (Miettinen et al., 1995; Murillas et al., 1995; Sibilia and Wagner, 1995; Threadgill et al., 1995; Sibilia et al., 2003), and anti-EGFR therapy in cancer patients commonly induces dermatologic side effects including xerotic itchy skin (Lacouture, 2006). Although these observations corroborate the significance of EGFR signaling in skin homeostasis, little is currently known about the role of EGFR signaling in maintaining the epidermal barrier and in suppressing chronic inflammatory skin disease.

ADAM17 (a disintegrin and metalloproteinase 17) is a membrane-anchored metalloproteinase that is a crucial upstream regulator of EGFR signaling (Peschon et al., 1998; Jackson et al., 2003; Sternlicht et al., 2005) and is responsible for the cleavage of pro-TNF (Black et al., 1997; Moss et al., 1997). Mice lacking ADAM17 die at birth, presumably as a result of defects in heart development, although other organs, such as the lung, skin, and mammary epithelia were also affected (Peschon et al., 1998; Jackson et al., 2003; Sternlicht et al., 2005). In that respect, Adam17−/− mice nearly phenocopy Egfr−/− mice or mice lacking the EGFR ligands TGF-α, HB-EGF, or amphiregulin, indicating an in vivo relevance of ADAM17 in EGFR processing (Peschon et al., 1998; Jackson et al., 2003; Blobel, 2005; Sternlicht et al., 2005). This notion is supported by cell-based assays, in which the shedding of several EGFR ligands depended on ADAM17 (Sahin et al., 2004). Moreover, ADAM17-dependent EGFR activation protects hepatocytes from apoptosis during drug-induced toxicity (Murthy et al., 2010) and supports intestinal proliferative regeneration in experimental colitis (Chalaris et al., 2010). Because very little is currently known about the role of ADAM17 in postnatal epithelial barrier homeostasis under physiological conditions, the goal of this study was to analyze how conditional inactivation of ADAM17 in keratinocytes (A17−/− KC) affects the development and maintenance of the epidermal barrier.

RESULTS

Keratinocyte-specific ADAM17 deficiency results in severe postnatal epidermal barrier defects

To analyze the function of ADAM17 in skin, we crossed mice with floxed alleles of ADAM17 (Horiuchi et al., 2007) with keratin14-Cre knockin mice (Krt14-Cre) to generate mice lacking ADAM17 in keratinocytes (A17−/− KC). Western blot analysis confirmed the deletion of ADAM17 in epidermal splits from A17−/− KC mice (Fig. 1A). An analysis of the expression pattern of Krt14-Cre using the ROSA26-lacZ reporter confirmed that it was restricted to the squamous epithelia.

Figure 2. Decreased TGM activity and altered expression of epidermal differentiation markers in A17−/− KC skin. of the skin and mucosa, as previously reported (Wang et al., 1997; not depicted).

Newborn A17KKC mice had no evident skin defects (Fig. 1 B) or histological abnormalities in their epidermis (not depicted). About 7.5% of A17KKC mice were born with open eyes (Fig. 1 B), whereas all Adam17+/− mice (complete knockout) have open eyes at birth (Peschon et al., 1998; Horiuchi et al., 2007), suggesting that other cells besides keratinocytes contribute to this phenotype in Adam17+/− mice. However, starting at P19, macroscopic epidermal defects became evident, with dry scaly skin in the face, the area surrounding the snout, the ventral neck and chest (Fig. 1 C), and the tail (not depicted), suggesting a compromised epidermal barrier in A17KKC mice.

Epidermal barrier defects lead to water loss, weight loss, electrolyte imbalances, and loss of skin turgor (Shwayder and Akland, 2005). Although the Mendelian distribution of the offspring of Adam17flx/flx/Krt14-Cre × Adam17flx/flx mice was normal (not depicted) and A17KKC mice had a normal weight compared with littermate controls at birth and the first days thereafter, their weight was reduced by 5% at postnatal day 8 (P8) and ~30% at P20 (Fig. 1 D). Most of the A17KKC mice died between P21 and P29, although some lived up to 6 mo (Fig. 1 E). The mean weight of surviving A17KKC mice was about half that of control animals (Fig. 1 D). Moreover, A17KKC mice had reduced skin turgor and significantly increased serum sodium levels (Fig. 1 F). The combination of hypernatremia and weight loss suggested dehydration as the underlying cause. None of the other genotypes (Adam17KRC/w/Krt14-Cre, Adam17flx/flx/Krt14-Cre, Adam17flx/flx, or Adam17flx/flx) referred to as Ctrl displayed any evident phenotype (unpublished data). Together, these data suggest that the postnatal lethality in A17KKC mice was caused by water loss as the result of an epidermal barrier defect that developed after birth.

We next used a dye penetration assay to examine the integrity of the skin barrier. The epidermis of newborn mice and P10 pups was completely resistant to toluidine blue penetration, whereas P15 animals showed dye permeability in the mechanically stressed areas, including the face around their snout, genitals, anus, and paws (Fig. 1 G). Transepidermal water loss (TEWL) of the skin surface was first detectable at P10, and subsequently increased with age, as documented at P15 and P19 (Fig. 1 H), indicating severe inside-out barrier defects. Because epidermal lipids are crucial to form the protective barrier against water loss in the stratum corneum, we stained P15 skin sections with the lipophilic dye Nile red. No significant differences in epidermal lipid content and distribution were seen in A17KKC versus control mice (unpublished data). Impaired integrity of the CE has been linked to skin barrier defects (Sevilla et al., 2007). CE preparations derived from P15 biopsies of A17KKC back skin showed 50% reduced size and were clustered in conglomerates that were not seen in preparations of control skin (Fig. 1 I), indicating abnormal development and an immature state.

### Dysregulated epidermal differentiation markers and decreased TGM activity in A17KKC skin

Skin integrity depends on the renewal of terminally differentiated keratinocytes, which assemble the CE. Histological analysis of back skin from A17KKC mice and littermate controls at P2 failed to uncover evident structural defects within the epidermal layers or differences in the number of proliferating basal keratinocytes (unpublished data). Instead, epidermal differentiation was significantly altered, with increased production of the early differentiation marker keratin 14, a structural component of the basal layer, remained unchanged (Fig. 2 A). Thus, epidermal ADAM17 deficiency increases early and dysregulates late keratinocyte differentiation.

The TGMs 1 and 3 are crucial to forming the CE (Hitomi, 2005). When we used a fluorometric in situ assay with a synthetic TGM substrate (Raghunath et al., 1998) to evaluate whether the TGM expression or activity was altered in A17KKC keratinocytes, we found comparable epidermal TGM activity to control littermates at P2 but significantly reduced activity in A17KKC epidermis at P10 (Fig. 2 B).

**Figure 3.** A17KKC keratinocytes exhibit cell autonomous dysregulated terminal differentiation

JEM Vol. 209, No. 6

Moreover, quantitative RT-PCR analysis revealed similar expression of both TGMs at P2 (not depicted) but significantly reduced expression at P10 in \( A17^{\Delta KC} \) skin compared with controls (Fig. 2 C). An immunoblot of P10 skin showed significant reduction of TGM3 in \( A17^{\Delta KC} \) animals but comparable TGM1 levels (Fig. 2 D). Finally, there was a thickened stratum corneum (not depicted) and elevated CE numbers in \( A17^{\Delta KC} \) skin (Fig. 1 I, right), similar to the hyperkeratinized stratum corneum with significantly improved TEWL found in TGM1\(^{-/-}\) skin grafts on nude mice as a compensatory mechanism for the skin permeability defects (Kuramoto et al., 2002).

Thickening of the cornified layer can be caused by reduced desquamation of corneocytes, which depends on processing by kallikreins (Eissa and Diamandis, 2008). When we probed \( A17^{\Delta KC} \) skin sections with fluorescently labeled soybean protease inhibitor (SBTI), which binds kallikreins (Franzke et al., 1996), we found significantly reduced staining in the \( A17^{\Delta KC} \) stratum corneum at P10 (Fig. 2 E). This indicates a strong reduction of serine protease activities, which can be caused by decreased protease expression or increased expression of inhibitors. A skin DNA microarray from P10 skin of \( A17^{\Delta KC} \) animals showed up-regulation of two serine protease inhibitors, serpina3a and a3n, compared with controls, which was confirmed by quantitative RT-PCR (Fig. 2 F).

Skin barrier defects in \( A17^{\Delta KC} \) animals induce IL-36\(\alpha\), immune cell influx, and hyperproliferative epidermis

The microarray analysis on P10 skin identified the IL-1 family member IL-36\(\alpha\) as the most prominent proinflammatory cytokine in \( A17^{\Delta KC} \) skin. A quantitative PCR (qPCR) analysis for several IL-1 family members (IL-1\(\alpha\), IL-1\(\beta\), IL-1ra, IL-36\(\alpha\), IL-36\(\beta\), IL-36Ra, IL-18, and IL-18bp) showed no elevation at P2 and P6, in contrast to the significant increase of the keratinocyte-derived cytokines IL-36\(\alpha\), IL-36\(\beta\), and IL-18 (Blumberg et al., 2007; Sims and Smith, 2010) at P10 (Fig. 4 A). qPCR from suspension culture of extracellular matrix (ECM)–disrupted primary \( A17^{\Delta KC} \) keratinocytes and controls (Wakita and Takigawa, 1999; Cheng et al., 2010). \( A17^{\Delta KC} \) keratinocytes showed significantly reduced levels of the TGMs 1 and 3 and concomitantly increased loricrin production (Fig. 3 A), suggesting cell-autonomous regulatory mechanisms. Furthermore, the TGM activity in \( A17^{\Delta KC} \) keratinocytes was strongly reduced in suspension cultures (Fig. 3 B).

Figure 4. Skin barrier defects result in increased IL-36\(\alpha\), immune cell infiltration, and epidermal thickening. ADAM17 is the principal sheddase for several ligands of the EGFR (Peschon et al., 1998; Jackson et al., 2003; Blobel, 2005; Sternlicht et al., 2005). Western blot analysis of phosphory-

EGFR in A17²⁴KC skin lysates with similar levels of total EGFR (Fig. 6 A). Egfr⁻⁻ mice have defects in hair and
penetrance of open eyes at birth, delayed hair outgrowth, shortened and disorganized hair follicles at P10, and dry scaly skin on the face, scalp, ventral upper trunk, and tail at P19 (unpublished data).

Egfr$^{-}$KC mice showed 85% lethality between P18 and P25, with survivors living up to 6 mo (Fig. 6 C) with pronounced growth retardation and a 50% of maximal weight loss (Fig. 6 D).

Egfr$^{-}$KC mice had significant dye penetration on the face, upper trunk, and paws at P15 (Fig. 6 E) and significant TEWL at P10, which was strongly elevated at P19 (Fig. 6 F). Similar to A17$^{-}$KC mice, we found a significant reduction of the late terminal differentiation marker involucrin in the Egfr$^{-}$KC epidermis (Fig. 6 G) and increased keratin1 and loricrin mRNA expression (not depicted). Moreover, TGM activity was unchanged in the epidermis of Egfr$^{-}$KC mice at P2 (not depicted) but significantly reduced at P10 compared with controls (Fig. 6 H). Analysis of cytokine expression in the skin of Egfr$^{-}$KC mice showed no elevation of IL-1$\alpha$, IL-1$\beta$, IL-1ra, and IL-36Ra, but significantly elevated IL-36$\alpha$ and Ccl2 at P12 (Fig. 6 I) and induction of Cxcl1, as well as strongly increased neutrophil and inflammatory macrophage infiltrates at P19 (Fig. 6, I and J; and not depicted). Thus the pathological changes in Egfr$^{-}$KC mice closely resembled those observed in A17$^{-}$KC mice.

Figure 6. Egfr$^{-}$KC mice have similar epidermal differentiation and barrier defects as A17$^{-}$KC mice. epithelial development (Miettinen et al., 1995; Sibilia and Wagner, 1995; Sibilia et al., 2003) resembling those in A17$^{-}$KC mice; however, the effects of EGFR deficiency on epidermal barrier and CE formation have not been previously investigated.

Previously described Egfr$^{-}$KC mice in a SV129/CL57BL6/FVB background were viable and fertile with wavy hair (Lee and Threadgill, 2009), although the severity of EGFR knockout mouse phenotypes depends on the genetic background (Sibilia and Wagner, 1995; Threadgill et al., 1995). Therefore, we generated Egfr$^{-}$KC mice in the SV129/CL57BL6 background of the A17$^{-}$KC mice. Lack of EGFR expression in epidermal splits was confirmed by immunoblot (Fig. 6 B). Furthermore, expression of ADAM17 in Egfr$^{-}$KC skin was comparable with littermate controls (unpublished data). Egfr$^{-}$KC mice developed very similar phenotypes to those of A17$^{-}$KC mice, including curly whiskers and a 10% pen
We therefore sought to determine whether TGF-α is involved in the differentiation of primary keratinocyte cultures. When we used a Ca²⁺-induced keratinocyte differentiation assay (Pillai and Bikle, 1991), we found that Ca²⁺ treatment increased the release of TGF-α from keratinocytes by ∼50% compared with untreated controls (Dlugosz et al., 1994; not depicted). When suspension cultures of keratinocytes (Wakita and Takigawa, 1999; Cheng et al., 2010) were treated with 30 ng/ml TGF-α for 48 h, we found significantly reduced keratin 1 and loricrin mRNA expression, whereas keratin 14 expression remained unchanged (Fig. 7 A). Thus, stimulation of the EGFR by TGF-α had the opposite effect on the keratinocyte differentiation markers keratin1 and loricrin as deletion of ADAM17 (Fig. 2 A). Importantly, the reduced TGM activity in ECM-disrupted A17 KC keratinocytes was nearly completely restored by recombinant TGF-α (Fig. 7 B), suggesting that the lack of EGFR activation is the major cause of the loss of TGM activity in ADAM17-deficient keratinocytes.

To address the role of ADAM17/TGF-α in epidermal barrier maintenance in vivo, we first determined whether TGF-α levels are altered in A17 KC skin. No differences in the RNA expression or protein staining were observed in the A17 KC animals compared with controls (unpublished data). In addition, no significant differences in the expression of HB-EGF, amphiregulin, and epiregulin mRNA were found in A17 KC mice versus controls (unpublished data). However, shedding of TGF-α from primary A17 KC keratinocytes was strongly reduced compared with controls (Fig. 7 C).

To determine whether the lack of TGF-α shedding from the epidermis was responsible for the skin barrier breakdown and subsequent skin inflammation, we applied recombinant TGF-α or DMSO as control daily to a defined area of A17 KC skin: from P8 to P19 and measured EGFR phosphorylation, TGM activity, compensatory serine protease activity, and immune cell infiltration. Western blot analysis revealed a pronounced increase of phospho-EGFR and TGM activity (arrows). Bar, 20 µm.

**The EGFR ligand TGF-α regulates epidermal differentiation**

The EGFR ligands whose shedding depends on ADAM17 (Sahin et al., 2004), TGF-α is mainly responsible for epidermal development and hair growth (Luetteke et al., 1993; Mann et al., 1993; Schneider et al., 2008). Quantitative analysis of RNA expression level of EGFR ligands in wild-type P2 skin revealed the highest levels for TGF-α, with fivefold more expression than HB-EGF and ∼2.5-fold more expression than amphiregulin or epiregulin (unpublished data).

**Chronic deficiency of keratinocyte-derived ADAM17 results in atopic dermatitis-like disease**

20% of the A17 KC mice survived up to 6 mo, thus allowing us to examine the chronic effects of keratinocyte-ADAM17 deficiency. Older A17 KC mice displayed all characteristic manifestations of a defective epidermal barrier and dehydration, including dry scaly skin, significantly increased serum
sodium, reduced skin turgor, and 50% weight loss (unpublished data). Furthermore, compared with control littersmates, they exhibited strong scratching as a sign of intense pruritus, which is characteristic of chronic dermatitis with epidermal barrier defects (Habif, 2009). Histological analysis confirmed altered epidermal differentiation, with increased expression of keratin 1 and loricrin and lower expression of involucrin, one of the initiator proteins in the cornification, suggesting dysregulated terminal differentiation (Fig. 9 A). Long-term surviving A17^ΔKC mice also demonstrated pronounced epidermal hyperproliferation, similar to A17^ΔKC animals at P21 (Fig. 4 F), with increased cell numbers, keratin14, keratin1, and epidermal staining of the hyperproliferation marker keratin 6, which is normally only produced in the midportion of the hair follicles of control skin (Fig. 9 A). In addition, toluidine blue staining and flow cytometry of back skin of 60-d-old mice revealed pronounced dermal accumulation of mast cells (Fig. 9 B), and strongly elevated numbers of inflammatory macrophages (CD45^−CD11b^−Ly6G^−F4/80^+^) and T cell populations (CD3^+^; not depicted). The epidermal thickening was most likely induced by the severe infiltration of inflammatory cells. The prolonged skin inflammation of the A17^ΔKC mice presumably also caused systemic defects with significantly increased serum concentrations of IgE und IgG1 (Fig. 9 C), splenomegaly (Fig. 9 D), and enlarged lymph nodes (not depicted), and severely decreased bone marrow B220^+^ populations (Fig. 9 E) in P60 A17^ΔKC mice compared with controls. Similar pathological changes were observed in the skin of P60 Egfr^ΔKC mice (Fig. 9 B–E), suggesting that impaired EGFR signaling causes these defects in A17^ΔKC mice.

**DISCUSSION**

The skin provides an important protective physical barrier, yet the molecular mechanisms responsible for maintaining this barrier remain poorly understood. Here we report that the ADAM17–EGFR signaling axis in keratinocytes regulates the integrity of the skin barrier by promoting terminal keratinocyte differentiation and the cross-linking activity of TGMs. Lack of ADAM17 in keratinocytes led to severe epidermal barrier defects, resulting in TEWL, inflammatory infiltrates, and increased mortality. ADAM17 regulates the skin barrier by controlling EGFR ligand shedding and EGFR signaling in keratinocytes, as indicated by lack of TGF-α shedding from A17^ΔKC keratinocytes and the similar phenotype of Egfr^ΔKC and A17^ΔKC mice. Notably, application of TGF-α to A17^ΔKC skin restored epidermal barrier integrity by stimulating skin TGM activity and thereby reducing immune infiltrates. Our findings highlight the essential role of the ADAM17–TGF-α (or other EGFR ligands)–EGFR signaling pathway in maintaining epidermal barrier homeostasis.

The integrity of the epidermal barrier depends on the continuous regeneration of the cornified layer. Cornification is a tightly controlled process, which requires coordinated keratinocyte proliferation, detachment, migration and cell death by terminal differentiation. A striking finding in the epidermis of the A17^ΔKC animals was the defect in terminal keratinocyte differentiation and cornified layer formation, which was very similar to that observed in Egfr^ΔKC mice. The release of the ADAM17 substrate and EGFR ligand TGF-α was increased in differentiating wild-type keratinocytes, and...
ADAM17 maintains skin barrier homeostasis | Franzke et al.

Our findings suggest that ADAM17/EGFR signaling in keratinocytes only plays a minor role in the development of an intact skin barrier in utero and in newborn mice but that it is crucial for the renewal of the CE in postnatal development and adults. Consistent with our findings of a normal epidermal barrier in newborn A17<sup>-/-</sup> KC and Egfr<sup>-/-</sup> KC mice, the TGM activity, necessary for cross-linking of proteins and formation of the CE, was normal at birth but significantly decreased at P10. Interestingly, control littermates had strongly elevated expression of TGM1 and TGM3 (unpublished data) and increased TGM activity at P10 compared with P2, suggesting an increased importance of TGMs in forming and maintaining the CE as the animals grow older. Consistent with this, about a threefold increase in TGM activity was detected in adult murine skin compared with P2 skin (Kagehara et al., 1994). The reduction of both TGM transcripts in A17<sup>-/-</sup> KC skin at P10 and in ADAM17 deficient keratinocytes indicate that both TGMs are regulated cell autonomously by EGFR signaling, as further corroborated by enhanced TGM expression and activity after treatment with TGF-β. Interestingly, the severity of autosomal recessive congenital ichthyosis, a disorder of keratinization caused by mutations in TGM1, correlated with the decrease in skin TGM activity (Akiyama et al., 2003).

The reduced TGM activity in A17<sup>-/-</sup> KC epidermis resulted in the production of an immature CE and denser stratum corneum with significantly increased numbers of corneocytes. The more severe phenotype of Egfr<sup>-/-</sup> and Adam17<sup>-/-</sup> knockout mice is most likely explained by the compounded effects of EGFR or ADAM17 deficiency in all tissues. Our findings suggest that ADAM17/EGFR signaling in keratinocytes only plays a minor role in the development of an intact skin barrier in utero and in newborn mice but that it is crucial for the renewal of the CE in postnatal development and adults. Consistent with our findings of a normal epidermal barrier in newborn A17<sup>-/-</sup> KC and Egfr<sup>-/-</sup> KC mice, the TGM activity, necessary for cross-linking of proteins and formation of the CE, was normal at birth but significantly decreased at P10. Interestingly, control littermates had strongly elevated expression of TGM1 and TGM3 (unpublished data) and increased TGM activity at P10 compared with P2, suggesting an increased importance of TGMs in forming and maintaining the CE as the animals grow older. Consistent with this, about a threefold increase in TGM activity was detected in adult murine skin compared with P2 skin (Kagehara et al., 1994). The reduction of both TGM transcripts in A17<sup>-/-</sup> KC skin at P10 and in ADAM17 deficient keratinocytes indicate that both TGMs are regulated cell autonomously by EGFR signaling, as further corroborated by enhanced TGM expression and activity after treatment with TGF-β. Interestingly, the severity of autosomal recessive congenital ichthyosis, a disorder of keratinization caused by mutations in TGM1, correlated with the decrease in skin TGM activity (Akiyama et al., 2003).

The reduced TGM activity in A17<sup>-/-</sup> KC epidermis resulted in the production of an immature CE and denser stratum corneum with significantly increased numbers of corneocytes. The strongly reduced serine protease activity in the cornified TGF-β stimulated the differentiation of suprabasal-like keratinocytes, as indicated by reduced keratin 1 and loricrin and increased TGM expression (Dlugosz et al., 1994; Peus et al., 1997; Wakita and Takigawa, 1999; Cheng et al., 2010). Accordingly, A17<sup>ΔKC</sup> keratinocytes had increased loricrin levels and decreased TGM expression. These findings implicate ADAM17 in cell-autonomous regulation of keratinocyte differentiation and regeneration of the cornified layer through shedding of TGF-α.

Previous studies revealed immature or absent keratinization of the stratum corneum in newborn Egfr<sup>-/-</sup> mice (Miettinen et al., 1995; Sibilia and Wagner, 1995). In contrast, in our study both A17<sup>ΔKC</sup> and Egfr<sup>ΔKC</sup> animals were born with normal epidermal barrier integrity. The severe inside-out barrier defects with significant TEWL and the outside-in barrier defects only became evident around postnatal day 10. The more severe phenotype of Egfr<sup>-/-</sup> and Adam17<sup>-/-</sup> knockout mice is most likely explained by the compounded effects of EGFR or ADAM17 deficiency in all tissues. Our findings suggest that ADAM17/EGFR signaling in keratinocytes only plays a minor role in the development of an intact skin barrier in utero and in newborn mice but that it is crucial for the renewal of the CE in postnatal development and adults. Consistent with our findings of a normal epidermal barrier in newborn A17<sup>-/-</sup> KC and Egfr<sup>ΔKC</sup> mice, the TGM activity, necessary for cross-linking of proteins and formation of the CE, was normal at birth but significantly decreased at P10. Interestingly, control littermates had strongly elevated expression of TGM1 and TGM3 (unpublished data) and increased TGM activity at P10 compared with P2, suggesting an increased importance of TGMs in forming and maintaining the CE as the animals grow older. Consistent with this, about a threefold increase in TGM activity was detected in adult murine skin compared with P2 skin (Kagehara et al., 1994). The reduction of both TGM transcripts in A17<sup>ΔKC</sup> skin at P10 and in ADAM17 deficient keratinocytes indicate that both TGMs are regulated cell autonomously by EGFR signaling, as further corroborated by enhanced TGM expression and activity after treatment with TGF-β. Interestingly, the severity of autosomal recessive congenital ichthyosis, a disorder of keratinization caused by mutations in TGM1, correlated with the decrease in skin TGM activity (Akiyama et al., 2003).
layer is likely a consequence of the decreased TGM activity because serine protease and TGM activity were normal in P2 $A^{7\Delta KC}$ skin. Previous studies have shown that a reduced integrity of the cornified layer can be associated with a compensatory decrease in desquamation, resulting in a thickened stratum corneum that maintains skin barrier function. This effect has been documented in $Tgu^{-/-}$ skin grafts on nude mice, which formed a hyperkeratotic stratum corneum with significantly reduced TEWL (Kuramoto et al., 2002). Desquamation is an active process, which depends on a well balanced degradation of the corneodesmosomal adhesion molecules by the serine proteases kallikrein 7 and 5, which in turn are activated by other kallikreins (Eissa and Diamandas, 2008). Thus the decreased serine protease activity in the $A^{7\Delta KC}$ skin is most likely responsible for the reduced desquamation. Interestingly, kallikreins were not down-regulated in microarrays of $A^{7\Delta KC}$ skin (unpublished data) but instead serpina3 members were up-regulated, which can irreversibly inhibit several kallikreins and thereby regulate corneocyte detachment (Caubet et al., 2004; Ny and Egelrud, 2004; Baker et al., 2007).

The expression of proinflammatory cytokines in keratinocytes was most likely triggered by epidermal barrier defects because it increased at the same time that significant TEWL on the skin surface first became apparent and coincided with reduced TGM activity in $A^{7\Delta KC}$ skin. Previous studies have shown that acute skin barrier defects led to epithelial cytokine production, especially of IL-1 family members (Wood et al., 1992; Ye et al., 2002; Yang et al., 2010). We found that skin barrier defects in $A^{7\Delta KC}$ preferentially up-regulated the expression of the novel IL-1 family member IL-36α (Sims and Smith, 2010) and, to a lesser degree, IL-36β and IL-18. We detected similar IL-1 family member expression patterns in the skin of $Egfr^{A17\Delta KC}$ animals. The proinflammatory effects of IL-36α have been demonstrated in vivo by transgenic overexpression of IL-36α in the epidermis (Blumberg et al., 2007) and by the development of generalized pustular psoriasis in patients with an inactivating mutation in the IL-36 receptor antagonist (IL-36Ra), a protein which normally blocks activation of the IL-36 receptor (also referred to as IL-1 receptor-related protein type 2; IL-1Rrp2) by IL-36α, β, and γ (Marrakchi et al., 2011). Interestingly, pronounced epidermal expression of IL-36β was previously reported in epidermis-specific FGFR1/FGFR2 double knockout mice, which develop progressive skin barrier defects associated with immune cell infiltrates, comparable with the $A^{7\Delta KC}$ mice (Yang et al., 2010). Recent studies have shown that the FGFR2 activates the EGFR and ERK1/2 by stimulating ADAM17 and release of EGFR ligands, providing a possible explanation for the similar phenotypes of FGFR1/FGFR2 double knockout mice and $A^{7\Delta KC}$ mice (Maretzky et al., 2011). Thus, our findings support a model in which EGFR signaling in the epidermis has immunoregulatory functions by maintaining terminal keratinocyte differentiation.

Over time, the surviving $A^{7\Delta KC}$ mice developed a chronically thickened epidermis, dry skin, severe inflammatory dermal infiltrates, and systemic myeloproliferative disease. Murthy et al. (2012) recently described a similar inflammatory skin phenotype in $A^{7\Delta KC}$ mice but proposed that it is caused by the loss of a putative ligand-independent Notch activation by ADAM17, which, in turn, would normally suppress the production of thymic stromal lymphopoietin (TSLP) in adult skin. However, another study has shown that TSLP is produced as a consequence of skin barrier defects in general and does not depend on loss of Notch signaling (Demehir et al., 2008). Importantly, we demonstrate that the invasion of inflammatory cells is a consequence of the skin barrier defects, and not the cause, because skin defects develop in $A^{7\Delta KC}$ mice before inflammatory infiltrates and are not reversed by macrophage depletion with clodronate. Moreover, our study identifies EGFR-dependent regulation of TGMs, which are directly responsible for establishing the skin barrier, as the most likely basis of the skin defect in $A^{7\Delta KC}$ mice. This mechanism is further supported by the finding that $Egfr^{A17\Delta KC}$ mice develop chronic dermatitis and systemic myeloproliferative disease, just like $A^{7\Delta KC}$ mice, and by rescue experiments of $A^{7\Delta KC}$ mice with the EGFR ligand and ADAM17 substrate TGF-α. Therefore, we conclude that chronic dermatitis and systemic myeloproliferation in ADAM17 knockout mice are late manifestations of persistent EGFR ligand deficiency and the resulting defective skin barrier. In this context, it should also be noted that previous studies have demonstrated both agonistic and antagonistic cross talk between the EGFR and Notch pathways (Yoo et al., 2004; Hasson et al., 2005; Doroquez and Rebay, 2006; Aguirre et al., 2010), suggesting that the reduced Notch signaling observed by Murthy et al. (2012) in $A^{7\Delta KC}$ skin could also be explained by lack of EGFR activation. Finally, both $A^{7\Delta KC}$ and $Egfr^{A17\Delta KC}$ mice showed an outside-in barrier defect, which is thought to contribute to the pathogenic mechanism of atopic dermatitis by exposing the skin to exogenous agents or antigens, which then trigger immune reactions (Irving and McLean, 2006; Moniaga et al., 2010).

Of the EGFR ligands that are shed by ADAM17 (Sahin et al., 2004), TGF-α is the principal growth factor required for epidermal differentiation and hair growth in mice (Luetteke et al., 1993; Mann et al., 1993) and it is the most highly expressed EGFR ligand in skin. However, other EGFR ligands also regulate important keratinocyte functions, such as keratinocyte migration, which is stimulated by heparin binding EGF (HB-EGF) and increased keratinocyte proliferation in psoriasis-like cutaneous pathologies by amphiregulin (Schneider et al., 2008; Maretzky et al., 2011). It is therefore possible that several ADAM17-dependent EGFR ligands coordinately support epidermal barrier development and maintenance.

The EGFR signaling pathway is an established target for treatment of various cancers (Hynes and Lane, 2005). Interestingly, dermatologic side effects frequently appear during the first 3 wk of treatment, especially on skin regions with high density of sebaceous glands, like the scalp, face, and upper chest. These side effects include inflammatory papulopustular acneiform rash, hair changes, itching (pruritus), and skin dryness (xerosis), whereas the mostly sterile inflammatory rash
accompanying with itchy xerotic skin is the most frequent manifestation (Pastore and Mascia, 2008; Lacouture et al., 2011). Recently, similar anti-EGFR antibody-induced neutrophil-rich skin inflammation combined with epithelial thickening of the face and upper trunk has been reported in immunodeficient (SCID) mice after the 3rd wk of treatment (Suruladze et al., 2009). Although the clinical manifestations are well characterized, the direct mechanistic cause of these inflammatory skin reactions is still unclear (Lacouture, 2006). Because depletion of ADAM17 or the EGFR in the epidermis lead to xerotic inflammatory skin, preferentially at sites with high density of sebaceous glands, it is likely that the gene-targeted mice and patients share the same mechanistic cause of epidermal pathology. This notion is further supported by a recent report of the first inactivating mutation in the ADAM17 gene borne by a human patient, who has developed an inflammatory skin and bowel disease with neonatal onset, strongly elevated T cell skin infiltrates, and reduced TGM1 expression in the skin (Blaydon et al., 2011). Thus, the insights gained from Adam17−/− mice have significant translational relevance. Understanding the biological consequences of the blockage of ADAM17-dependent EGFR signaling in the skin could lead to the development of better therapeutic strategies for the dermatologic side effects of EGFR antagonists in cancer patients and the treatment of patients carrying mutant alleles of ADAM17.

MATERIALS AND METHODS

Animals. The generation of Adam17flox/flox and Egrflox/flox mice has been described previously (Horuchi et al., 2007; Lee and Threadgill, 2009). Both strains were crossed with keratin-14-Cre (Krt14-Cre) transgenic mice (004782, STOCK Tg(KRT14­cre)1Amc/J; The Jackson Laboratory). Adam17−/−/Krt14-Cre mice were crossed with Adam17flox/flox mice to generate Adam17flox/−/Krt14-Cre mice, referred to as Adam17flox/−. An essentially identical approach yielded Egfrflox/−/Krt14-Cre mice, referred to as Egfrflox/−. In both cases, the genotypes of the offspring followed a Mendelian distribution. Transgenic ROSA26-LacZ reporter mice were from The Jackson Laboratory (003309, B6.129S4-Gr(Rosa)26Sor1(Sor); all mice were of mixed genetic background (129Sv, C57BL/6), and all comparisons were between littermates. Serum sodium concentrations were measured on a Chemistry Analyzer (AU400; Beckman Coulter). In some experiments, mice received daily applications of TGF-α (1.5 µg/mouse) or vehicle (80% DMSO in PBS) on their ventral neck and one ear. For depletion of skin macrophages, we subcutaneously injected 100 µl of Clodronate-loaded liposomes or PBS-loaded liposomes as control every other day into the back skin of Adam17flox/− or Egfrflox/− mice and their wild-type littermates essentially as described (Franzke et al., 2009). In brief, the skin was washed with PBS containing 1% antibiotic-antimycotic (Invitrogen, Germany), and epidermis and dermis were detached by overnight digestion with dispase (STEMCELL Technologies) at 4°C. The epidermis was incubated with 0.25% trypsin (wt/vol) and 2 mM EDTA for 30 min at 37°C under vigorous shaking. After stopping the reaction with PBS containing 10% FCS, the keratinocyte suspension was passed through a 45-µm sieve, and 105 cells/cm2 were plated in defined serum-free keratinocyte medium (CelliTec) supplemented 100 U/ml penicillin and 100 µg/ml streptomycin (Invitrogen). The cells were maintained in defined serum-free keratinocyte medium at 37°C in 5% CO2, and medium was replaced every 48 h. Subconfluent cells derived from passages 1–3 were used for the experiments.

Keratinocyte cell suspension cultures. Suspension culture on poly-hydroxyethyl-methacrylate (poly-HEMA)-coated plates was performed as previously described (Wakita and Takigawa, 1999). 6-well plates were coated with poly-HEMA (Sigma-Aldrich), followed by extensive PBS washes. 2 ml of cell suspension was added in each coated well and incubated in a humidified incubator with 5% CO2 in air at 37°C for 24 or 48 h. After centrifugation the cell pellets were either used for the preparation of cell lysates or total RNA extraction or for the in vitro detection of TGM activity. For the detection of TGM activity, we attached 24-h suspension-cultured keratinocytes on gelatin-coated coverslips and preincubated them with 1% BSA in 0.1M Tris–HCl, pH 7.4, for 30 min at room temperature. Afterward, we detected the TGM activity as described in the Enzyme activity assays section.

Histology. Tissues were fixed in 3.7% buffered formaldehyde or 4% PFA and embedded in paraffin. 5-µm sections were stained with hematoxylin and eosin (H&E) and toluidine blue.

Immunohistochemistry. Paraffin sections or cryosections of 5 µm were stained using mAb against Ki67 (1:50; clone TEC-3; Dako), keratin 14 (1:200; clone LL001; Santa Cruz Biotechnology, Inc.), and polyclonal rabbit antibodies against human TGF-α (1:50; R&D systems), keratin1 (1:1,000; Abcam), Iorcin (1:1,000; GenEx), keratin 6, involucrin (1:500; Covance), and TGM1 and TGM3 (both 1:100; Santa Cruz Biotechnology, Inc.). For visualization, the sections were incubated with either biotinylated secondary anti-mouse IgG or anti-rabbit IgG antibodies (Dako) using the VECTASTAIN ABC kit and Nova RED substrate kit (Vector Laboratories) or with Alexa Fluor 488- or Alexa Fluor 594-conjugated secondary antibodies (Invitrogen), followed by embedding with mounting medium supplemented with DAPI (Vector Laboratories). Epidermal lipids in skin cryosections were visualized using 2.5 µg/ml Nile red for 2 min at RT. Specimens were viewed with a brightfield and epifluorescence microscope (Axio Imager A1 equipped with AxioCam MRm and MRc cameras; Carl Zeiss) using AxioVision software (version 4.8.2; Carl Zeiss) and processed using ImageJ software (version 1.43u; National Institutes of Health).

Tissue histology of the Krt14-Cre/ROSA26-LacZ reporter mice. The tissue expression pattern of the keratin 14 promoter was analyzed using offsprings of matings of Adam17flox/flox/Krt14-Cre mice with Adam17flox/flox ROSA26-lac-Z mice (R26R), which express β-galactosidase under Cre-mediated excision of a loxP-flanked STOP codon. The tissues taken from P14 or P28 animals were fixed with 4% PFA in PBS for 2 h and incubated with 5-bromo-4-chloro-3-indolyl β-d-galactosidase staining solution at 37°C overnight, and subsequently embedded in paraffin. The tissue sections were counterstained with eosin.

Quantitative RT-PCR analysis. Total RNA from mouse skin, epidermal splits, or primary keratinocyte cultures was extracted using R.Naasy (QIAGEN). 1 µg of total RNA was reverse transcribed using a First Strand cDNA Synthesis kit (Fermentas). Relative quantification of gene expression was performed by real-time qPCR using iQ SYBR-green Supermix on a Thermal Cycler (CFX96 C1000; Bio-Rad Laboratories) according to the manufacturer’s protocols. All primer sequences are shown in Table S1. Relative expression was normalized for levels of GAPDH. The generation of the correct amplification products was confirmed using agarose gel electrophoresis.

Primary keratinocyte preparation and cultivation. Keratinocytes were isolated from the skin of A17flox/− or Egfrflox/− mice and their wild-type littermates essentially as described (Franzke et al., 2009). In brief, the skin was washed with PBS containing 1% antibiotic-antimycotic (Invitrogen, Germany), and epidermis and dermis were detached by overnight digestion with dispase (STEMCELL Technologies) at 4°C. The epidermis was incubated with 0.25% trypsin (wt/vol) and 2 mM EDTA for 30 min at 37°C under vigorous shaking. After stopping the reaction with PBS containing 10% FCS, the keratinocyte suspension was passed through a 45-µm sieve, and 105 cells/cm2 were plated in defined serum-free keratinocyte medium (CelliTec) supplemented 100 U/ml penicillin and 100 µg/ml streptomycin (Invitrogen). The cells were maintained in defined serum-free keratinocyte medium at 37°C in 5% CO2, and medium was replaced every 48 h. Subconfluent cells derived from passages 1–3 were used for the experiments.
Immunoblotting. For Western blot analysis, the samples were processed as previously described (Franzke et al., 2009). The cells and tissues were lysed in 25 mM Tris-HCl, 1% Nonidet P-40, and 0.1 M NaCl, pH 7.4, supplemented with 2 mM EDTA, 5 mM 1,10-orthophenanthroline (Sigma-Aldrich), and protease inhibitor cocktail set III (EMD). Epidermal sheets were detached from the dermis by digestion with dispase (STEMCELL Technologies) at 37°C. Tissues were homogenized in lysis buffer on ice with a T18 basic Ultra Turrax (Ika). Total protein content was determined using the BCA protein assay kit (Invitrogen) and 25 µg total protein per sample was separated by electrophoresis on 7% or 10% SDS-polyacrylamide gels. Immunoblots were probed with anti-keratin 14 mAb (Santa Cruz Biotechnology, Inc.), anti-EGFR rabbit pAbs (Cell Signaling Technology) or anti-phospho-EGFR (pY1068, clone EP774Y; Epitomics Inc.), polyclonal rabbit antibodies against the cytoplasmic domain of ADAM17 (Schlöndorff et al., 2000), TGM1, TGM3, and Erk1/2 (Santa Cruz Biotechnology, Inc.), phospho-p44/42 MAPK (Thr202/Tyr204; Cell Signaling Technology Inc.), keratin1 (Abcam), loricrin (GeneTex, USA) and involucrin (Corvance), and secondary HRP-coupled anti-mouse and anti-rabbit IgG antibodies. Immunoblot signals were quantified using Fusion SL and BIO-ID Advanced software (PegLab Biotechnologie GmbH).

Enzyme activity assays. For in situ detection of TGM activity in skin sections, we used the biotinylated amine donor substrate monodansylcadaverine (biotMDC) as described earlier (Raghunath et al., 1998). Cryostat sections were air dried and preincubated with 1% BSA in 0.1 M Tris-HCl, pH 7.4 or pH 8.4, for 30 min at room temperature. The sections were then incubated for 2 h with 100 µM biotMDC, 5 mM CaCl2, 0.1 M Tris-HCl, pH 7.4 (for TGM1) or pH 8.4 (for TGM1 and TGM3). After stopping the reaction with 10 mM EDTA and extensive PBS washing, the sections were stained with Streptavidin-conjugated Alexa Fluor 488 (Invitrogen) and DAPI-supplemented mounting medium. For in situ detection of serine protease activity in cryostat sections of skin, we incubated 0.5 µg/ml of the SBTI Alexa Fluor 488 conjugate in 1% BSA in 0.1 M Tris-HCl, pH 7.4, for 20 min at room temperature. Negative controls were incubated with excess concentrations of uncoupled SBTI. After extensive washing, the sections were processed with DAPI-supplemented mounting medium.

ELISA. TGF-α released from confluent keratinocytes in a 3.5-cm cell culture plate for 24 h was measured with an ELISA kit for human TGF-α (RayBioTech, Inc.) according to the manufacturer’s protocols. The supernatants were concentrated by 70% ethanol precipitation. Ig isotype sandwich ELISAs were performed by standard procedures. 96-well microtiter plates (NUNC) were air dried and preincubated with 1% BSA in 0.1 M Tris-HCl, pH 7.4, or 0.1 M Tris-HCl, pH 8.4 (for TGM1). Streptavidin-conjugated Alexa Fluor 488 (Invitrogen) and DAPI-supplemented mounting medium. The raw data were analyzed using GeneSpring GX 10.0 (normalization: shift to 75th percentile, baseline transformation: median of all samples). The normalized data were filtered to exclude probes flagged absent in all samples. The remaining probes were tested for statistical significance of expression using a two-sample Student’s t test (unpaired) with asymptotic p-value computation and a cut off of 0.05. Multiple testing correction was performed according to Benjamin-Hochberg (Kleiner-Aurbach et al., 1995; P ≤ 0.05). The cutoff for the fold change is ≤2 (1 log2) up- or down-regulation.

Statistics. All parametric data are present as mean ± SD. Data of two groups were analyzed for significance using the Student’s t test and the statistical analysis of survival curves was performed using the Mantel-Cox test. Both calculations were performed with Prism version 5.0 (GraphPad Software). For all analyses, n = number of experiments, and differences are considered to be statistically significant at P < 0.05.

Online supplemental material. Table S1 lists the primer sequences used for quantitative RT-PCR analyses. Online supplemental material is available at http://www.jem.org/cgi/content/full/jem.20112258/DC1.

We thank Elin Mogollon and Björn Wienke for excellent technical assistance, Elvira Brucker for determining serum sodium levels, Britta Dorn for Ig isotype analysis, and Dr. Kristina Beck for advice on B-cell FACS analysis. Clodronate (Clp) was a gift from Roche.
