Mammalian spermatogenesis is an elaborately organized differentiation process, starting with diploid spermatogonia, which include germ-line stem cells, and ending with haploid spermatozoa. The process involves four pivotal transitions occurring in physical proximity: spermatogonial differentiation, meiotic initiation, initiation of spermatid elongation, and release of spermatozoa. We report how the four transitions are coordinated in mice. Two premeiotic transitions, spermatogonial differentiation and meiotic initiation, were known to be coregulated by an extrinsic signal, retinoic acid (RA). Our chemical manipulations of RA levels in mouse testes now reveal that RA also regulates the two postmeiotic transitions: initiation of spermatid elongation and spermatozoa release. We measured RA concentrations and found that they changed periodically, as also reflected in the expression patterns of an RA-responsive gene, STRA8; RA levels were low before the four transitions, increased when the transitions occurred, and remained elevated thereafter. We found that pachytene spermatocytes, which express an RA-synthesizing enzyme, Aldh1a2, contribute directly and significantly to RA production in testes. Indeed, chemical and genetic depletion of pachytene spermatocytes revealed that RA from pachytene spermatocytes was required for the two postmeiotic transitions, but not for the two premeiotic transitions. We conclude that the premeiotic transitions are coordinated by RA from Sertoli (somatic) cells. Once germ cells enter meiosis, pachytene spermatocytes produce RA to coordinate the two postmeiotic transitions. In combination, these elements underpin the spatiotemporal coordination of spermatogenesis and ensure its prodigious output in adult males.

Author contributions: T.E., D.G.d.R., and D.C.P. designed research; T.E. and E.F. performed research; T.E., E.F., and D.G.d.R. analyzed data; and T.E. and D.C.P. wrote the paper.

Significance

Male mouse sex cells mature into sperm through a 35-d process punctuated by four transitions, two occurring before meiosis (spermatogonial differentiation and meiotic initiation) and two after meiosis (spermatid elongation and sperm release). The four transitions occur in proximity spatially and temporally, with an 8.6-d periodicity. We describe how this coordination is achieved. The premeiotic transitions were known to be regulated by retinoic acid (RA). We show that RA also regulates the two postmeiotic transitions. RA levels change periodically, and meiotic cells contribute to its production. The two postmeiotic transitions require RA from meiotic cells while the premeiotic transitions require RA from somatic cells. These elements underpin the spatiotemporal coordination of spermatogenesis to ensure constant sperm production throughout adult life.

of vitamin A. In vitamin A-deficient (VAD) mice and rats, most germ cells arrest as undifferentiated spermatogonia (17, 18). In VAD rat testes, some germ cells also arrest just before meiosis, as preleptotene spermatocytes (19). When VAD animals are given RA or vitamin A, the arrested spermatogonia differentiate (17–19), and the arrested preleptotene spermatocytes initiate meiosis (19). Moreover, deficiency of the RA target gene Stimulated by retinoic acid gene 8 (Stra8), which is expressed exclusively in germ cells (20, 21), causes the failure of meiotic initiation and accumulation of undifferentiated spermatogonia (7, 8, 22). Using Stra8 as an RA-responsive marker to predict RA levels, we previously reported that rising RA levels coordinate the two premeiotic transitions (22).

Given that the two postmeiotic transitions—initiation of spermatid elongation and release of spermatooza—coincide with high RA levels, we considered the possibility that RA might also regulate these two transitions. Indeed, ablation of RA receptors (RARs) or RA-synthesizing enzymes (in germ cells and/or Sertoli cells) cause a variety of modest defects in meiotic and postmeiotic aspects of spermatogenesis, including release of spermatooza (23–29). Nonetheless, the specific steps in meiotic progression or postmeiotic differentiation that RA might regulate have not been established. Moreover, the identity of the cells that supply the RA responsible for these four transitions remains unclear. To explore these questions empirically, we reasoned that we would also need to measure the absolute concentration of RA in testes under a range of experimental conditions.

We first chemically manipulated RA levels in living testes to probe whether RA induces the release of spermatooza. To ensure the efficacy of our experimental protocols, we first confirmed that i.p. injection of exogenous RA raises the concentration of RA in testes, and, conversely, that injection of WIN18,446, an inhibitor of RA synthesis (30), lowers RA levels in testes. We monitored RA levels in testes both indirectly, by immunostaining for STRA8 as an RA-responsive marker (20, 31, 32), and directly, by measuring RA levels via liquid chromatography/mass spectrometry (LC/MS). In control testis sections, STRA8 protein was not detectable in germ cells in seminiferous stages V and VI (before key transitions) but was clearly present in spermatogonia and preleptotene spermatocytes in stages VII and VIII (during key transitions) (22) (Fig. S2A). As expected, at 1 d after a single RA injection, STRA8 was strongly induced in stages V and VI. Conversely, after 2 d of daily WIN18,446 injections, STRA8 was not expressed in stages VII and VIII. LC/MS assays confirmed that RA concentrations in testes were markedly increased 1 d after RA injection and markedly decreased after 2 or 4 d of daily WIN18,446 injection (Fig. 2A).

In the unperturbed testis, spermatooza are released in late stage VIII (Fig. 1). If RA induces this release, then WIN18,446 injection should increase the percentage of seminiferous tubules that contain aligned spermatooza, which are located along the luminal edge of the seminiferous tubules and are awaiting release into the lumen (Fig. S1D). Indeed, this is what we observed: After 2 or 4 d of daily WIN18,446 injection, the percentage of tubule cross-sections containing aligned spermatozoa was increased (Fig. 2B–D, Fig. S2B–E, and SI Results); release of spermatozoa was inhibited not only in late stage VIII but also in stages IX and X (Fig. 2E and Fig. S2F). If this inhibition of spermatozoa release is a consequence of RA depletion, then injection of RA might be expected to induce premature release of spermatozoa. Indeed, at 2 d after a single RA injection, the percentage of tubules containing aligned spermatozoa was decreased, particularly in stage VIII (Fig. 2B–D and Fig. S2B–E). We conclude that RA induces the release of spermatozoa.

**Results**

RA **Induces Release of Spermatozoa.** We chemically manipulated RA levels in living testes to probe whether RA induces the release of spermatozoa. To ensure the efficacy of our experimental protocols, we first confirmed that i.p. injection of exogenous RA raises the concentration of RA in testes, and, conversely, that injection of WIN18,446, an inhibitor of RA synthesis (30), lowers RA levels in testes. We monitored RA levels in testes both indirectly, by immunostaining for STRA8 as an RA-responsive marker (20, 31, 32), and directly, by measuring RA levels via liquid chromatography/mass spectrometry (LC/MS). In control testis sections, STRA8 protein was not detectable in germ cells in seminiferous stages V and VI (before key transitions) but was clearly present in spermatogonia and preleptotene spermatocytes in stages VII and VIII (during key transitions) (22) (Fig. S2A). As expected, at 1 d after a single RA injection, STRA8 was strongly induced in stages V and VI. Conversely, after 2 d of daily WIN18,446 injections, STRA8 was not expressed in stages VII and VIII. LC/MS assays confirmed that RA concentrations in testes were markedly increased 1 d after RA injection and markedly decreased after 2 or 4 d of daily WIN18,446 injection (Fig. 2A).

In the unperturbed testis, spermatozoa are released in late stage VIII (Fig. 1). If RA induces this release, then WIN18,446 injection should increase the percentage of seminiferous tubules that contain aligned spermatozoa, which are located along the luminal edge of the seminiferous tubules and are awaiting release into the lumen (Fig. S1D). Indeed, this is what we observed: After 2 or 4 d of daily WIN18,446 injection, the percentage of tubule cross-sections containing aligned spermatozoa was increased (Fig. 2B–D, Fig. S2B–E, and SI Results); release of spermatozoa was inhibited not only in late stage VIII but also in stages IX and X (Fig. 2E and Fig. S2F). If this inhibition of spermatozoa release is a consequence of RA depletion, then injection of RA might be expected to induce premature release of spermatozoa. Indeed, at 2 d after a single RA injection, the percentage of tubules containing aligned spermatozoa was decreased, particularly in stage VIII (Fig. 2B–D and Fig. S2B–E). We conclude that RA induces the release of spermatozoa.

RA **Promotes Initiation of Spermatid Elongation.** We then tested whether RA also affects spermatid elongation, the other key postmeiotic transition (Fig. 1). In the unperturbed testis, spermatid development has been subdivided into 16 steps; step 8 round spermatids initiate their elongation in stage VIII and become step 9 elongating spermatids in stage IX (Fig. 1). If RA induces this initiation of spermatid elongation, then WIN18,446 injection should increase the percentage of seminiferous tubules that contain step 7 and 8 round spermatids. Indeed, following 2 or 4 d of daily WIN18,446 injection, the percentage of tubules containing step 7 and 8 round spermatids was increased, and the percentage of tubules containing step 9 and 10 elongating spermatids was correspondingly decreased (Fig. 3A and B). Extending these daily injections to 21 d resulted in a nearly complete arrest at step 7 and 8 round spermatids (Fig. S3A and SI Results). By contrast, at 2 d after a single RA injection, the percentage of tubules containing step 7 and 8 round spermatids was decreased, and the percentage of tubules containing step 9 and 10 elongating spermatids was correspondingly increased (Fig. 3A and B). These quantitative results indicate that initiation of spermatid elongation is regulated by RA.

We next used pulse-chase labeling (33, 34) to confirm that RA causes spermatid elongation to be initiated earlier than it would normally occur. When a single BrdU injection is given, BrdU is incorporated into cells in mitotic or premeiotic S phase. At 4 h after BrdU injection, the most advanced BrdU-labeled germ cells are

---

**Fig. 1.** Diagram of mouse spermatogenesis. Oakberg (10) identified 12 distinct cellular associations, called seminiferous stages I to XII. It takes 8.6 d for a section of seminiferous tubule, and the germ cells contained within, to cycle through all 12 stages (9). Four turns of this seminiferous cycle are required for a germ cell to progress from undifferentiated spermatogonium to spermatozoon ready to be released into tubule lumen. $A_{diff}$, differentiating type A spermatogonia; $A_{undiff}$, undifferentiated type A spermatogonia; $B$, type B spermatogonia; $D$, diplotene spermatocytes; $In$, intermediate spermatogonia; $L$, leptotene spermatocytes; $P$, pachytene spermatocytes; $Pl$, preleptotene spermatocytes; $SC2$, secondary spermatocytes; $Z$, zygotene spermatocytes. Steps 1 to 16, steps in spermatid differentiation. preleptotene spermatocytes that have undertaken premeiotic S and thereby initiated the meiotic program (Fig. S3 B and C). In the unperturbed tests, these BrdU-labeled preleptotene spermatocytes develop into step 8 round and step 9 and 10 elongating spermatids, respectively, 17.2 and 18.2 d after BrdU injection (Fig. 3C). We predicted that RA or WIN18,446 treatment would accelerate or delay spermatid development, respectively, 18.2 d after the BrdU labeling, when the most advanced BrdU-labeled germ cells in unperturbed testes have initiated spermatid elongation. To test this, we gave mice a single BrdU injection, followed by daily RA or WIN18,446 injection during spermatid development (Fig. 3C), and harvested the testes at 17.2 d (Exps. 1 to 3) or 18.2 d (Exps. 4 to 6). We found that, at 17.2 d after BrdU injection, the most advanced BrdU-labeled germ cells were step 8 round spermatids in control tests, and there was no acceleration or delay under RA or WIN18,446 treatment (Fig. S3 D and F). This demonstrates that RA does not affect the development of round spermatids, from step 1 to step 8. However, as predicted, at 18.2 d after BrdU injection, the most advanced BrdU-labeled germ cells, which were step 10 spermatids in controls, had developed further—into step 11 spermatids—in RA-treated tests whereas they were still step 9 spermatids in WIN18,446-treated tests (Fig. 3D and Fig. S3F). Taken together, these findings provide strong evidence that RA promotes the initiation of spermatid elongation.

**RA Has No Discernible Effect on Meiotic Progression.** Given that four of the five generations of spermatogenic cells undergo transitions coregulated by RA in stages VII and VIII (Fig. 1), we wondered whether the remaining cell type at these stages, pachytene spermatocytes, also undergoes RA-regulated development during meiotic progression.

We examined this possibility by pulse–chase labeling. We gave mice a single injection of BrdU, followed by daily RA or WIN18,446 injection during meiotic progression (Fig. 3C, Exps. 7 to 9), and harvested the testes at 12.6 d, when, in control tests, the most advanced BrdU-labeled germ cells have completed meiotic progression and become step 1 and 2 spermatids. At 12.6 d, there was no acceleration or delay under RA or WIN18,446 treatment (Fig. S3 E and F). These results indicate that RA does not affect meiotic progression as assayed histologically.

To verify that RA does not affect meiotic progression at the molecular level, we tested for key molecular features of meiotic progression by immunohistochemistry. We first gave mice a single injection of 5-ethyl-2’-deoxyuridine (EdU), followed by daily RA or WIN18,446 injection during meiotic progression (Fig. 4A), and harvested testes at 8.6 d (Exps. 10 to 12) and 11 d (Exps. 13 to 15), when in control tests the most advanced EdU-labeled germ cells have progressed to late pachytenne stage and diploteotes stage, respectively (35). We then immunostained the EdU-labeled nuclear spreads of spermatocytes for markers of meiotic prophase to distinguish among middle pachytenne, late pachytenne, and diploteotes stages. Specifically, we used antibodies against phosphorylated H2A histone family member X (pH2AX) (a marker of DNA double strand breaks and sex body formation) (36), synaptonemal complex protein 3 (SYCP3) (a marker of synaptonemal complex) (37), testis-specific histone (H1t) (a marker of middle/late pachytenne stages) (38), and ataxia telangectasia and Rad3-related protein (ATR) (a marker of DNA repair and sex body formation) (39). Based on these markers (SI Results), at 8.6 d and 11 d after EdU injection, the most advanced EdU-labeled germ cells in control testes were, respectively, late pachytenne and diploteotes spermatocytes, and there was no acceleration or delay after RA or WIN18,446 treatment (Fig. 4B–D and Fig. S4). Importantly, expression and localization of all of the meiotic markers appeared to be unaffected by either RA or WIN18,446 treatment. We conclude that RA has no discernible effect on meiotic progression from leptotene stage to diploteotes stage, including the development of pachytenne spermatocytes.

Our results demonstrate that RA regulates release of spermatozoa and initiation of spermatid elongation, as well as spermatogonial differentiation and meiotic initiation, but not meiotic progression, in stages VII and VIII. To explore the mechanism by which these four transitions are coordinated in time and space by RA, we next focused on changes in RA levels in the seminiferous tubules.
RA promotes initiation of spermatid elongation. (**P < 0.01, ***P < 0.001, *P < 0.05, Tukey’s test). (Fig. S1A and SI Results) and then injected a single dose of RA at P15, harvesting testes 5, 8, 9, or 10 d after the RA injection (Fig. S4A and Fig. S5B). As we anticipated, at 5 d after RA injection, when seminiferous tubules were synchronized at stages II to IV, the RA concentration was negligible or very low (Fig. S5B). Then, at 8 d, in stages VII to IX, the RA concentration was significantly increased, and it remained high at 9 d, in stages IX to XI, before falling modestly at 10 d, in stages XI to I (difference between RA levels in stages VII to IX and XI to I is not significant; P > 0.05, Tukey-Kramer test). We conclude that RA concentrations change periodically, as also reflected by, and in good agreement with, STRA8 expression patterns (Fig. S5C).

RA Concentration Increases When Aldh1a2-Expressing Pachytene Spermatocytes First Appear. We then considered the identity of the cells within the seminiferous tubules that produce RA. Sertoli cells, which have been shown to express an RA-synthesizing enzyme, aldehyde dehydrogenase 1A1 (Aldh1a1) (42, 43), are likely the source of the RA measured in the experiments just described. Another RA-synthesizing enzyme, Aldh1a2, is abundantly expressed in pachytene spermatocytes (and their descendants, diploctene spermatocytes) from stages VII through XII (42, 43). If pachytene spermatocytes actually produce RA from stage VII onward, then RA levels in the testes of young males should rise shortly after these Aldh1a2-expressing pachytene cells first appear (at about 15 d after RA-induced spermatogonial differentiation). To test this prediction, we harvested stage-synchronized testes at 12, 15, 16, and 17 d after RA injection, when pachytene and diploctene spermatocytes first appear (Fig. S4A and Fig. S5B), for absolute quantification of RA levels. At 12 d after RA injection, when seminiferous tubules containing pachytene spermatocytes were in stages II to IV, RA concentration was very low, similar to 5 d after RA injection (Fig. S5B and Fig. S5D). As predicted, at 15 d after RA injection, in stages VII to IX, RA concentration was increased and significantly higher than at 8 d, when pachytene spermatocytes were not yet present. The higher RA concentration was maintained at 16 d and 17 d after RA injection, the specific cohort of germ cells that normally would have transited to pachytene and diplote at stages I to XII was missing from the testis, as expected (Fig. S5C and Fig. S6B). In stage VII and VIII tubules, pachytene spermatocytes were the...
only missing cells, again as expected (Fig. 5D and Fig. S6C). Importantly, testicular RA concentrations were significantly lower than in controls (Fig. 5E and Fig. S6D and E). Also, as predicted, we observed that the remaining levels of RA, which probably derived from Sertoli cells, were eliminated by coinjection of WIN18,446 with HU. We conclude that conditional depletion of pachytene spermatocytes reduces RA levels in adult testes.

To confirm that the reduced RA concentration at 11.6 d after the first HU injection was associated with the depletion of a specific RA-synthesizing enzyme from seminiferous tubules, we carried out single-molecule fluorescence in situ hybridization (smFISH). Because smFISH probes detect and localize each target mRNA molecule as a punctate signal, these signals can be quantified to determine the number of transcripts per cell (47) (SI Results). In control stage VII and VIII tubules, Aldh1a2 was expressed specifically in pachytene spermatocytes, Aldh1a1 was expressed specifically in Sertoli cells, and Aldh1a3 was expressed at very low levels, if at all, in germ cells and Sertoli cells (Fig. 6), all as previously reported (42, 43); we used kidney as a positive control for genetic ablation of these genes in other contexts (48, 49). Consequently, HU depletion of pachytene spermatocytes did not result in reduced expression of Aldh1a1, Aldh1a2, or Aldh1a3 in the remaining germ or Sertoli cells. Thus, the reduction in RA concentration upon depletion of pachytene spermatocytes was not due to reduced expression of RA-synthesizing enzymes in the remaining cells of the seminiferous tubules. Instead, depletion of ALDH1A2-expressing pachytene spermatocytes reduces testicular RA concentrations directly. We then proceeded to test whether RA from pachytene spermatocytes contributes functionally to the four key transitions in stages VII and VIII, using HU-treated testes.

**RA from Pachytene Spermatocytes is Required for Postmeiotic, but Not for Premeiotic, Transitions.** If RA from pachytene spermatocytes is required for release of spermatocytes and initiation of spermatid elongation, seminiferous tubules should display accumulations of aligned (unreleashed) spermatooza and round (unelongated) spermatids, respectively, at 11.6 d after the first HU injection. Indeed, at 11.6 d after the first HU injection, seminiferous tubules displayed increased numbers of aligned spermatooza and step 7 and 8 round spermatids (Fig. 7A and B and Fig. S8 A–D). These accumulations of unreleased spermatooza and unelongated spermatids in response to HU were not exacerbated by coinjecting WIN18,446 with HU. Moreover, when a single dose of RA was injected 9.6 d after the first HU injection, the abnormal accumulations were cured, or rescued, at 11.6 d, indicating that the accumulations after pachytene spermatocyte depletion were due specifically to the resulting decrease in RA concentration. We conclude that RA from pachytene spermatocytes is required for initiation of spermatid elongation and for release of spermatooza.

We next tested whether RA from pachytene spermatocytes is required for meiotic initiation. At 11.6 d after the first HU injection, both preleptotene spermatocytes and type A spermatogonia in stages VII and VIII expressed Stra8 (transcripts) at levels similar to those of
controls (Fig. 6A and Fig. S7D), suggesting that these germ cells are responding normally, even in the absence of pachytene spermatocytes and the RA that they provide. If RA from pachytene spermatocytes is not required for meiotic initiation, then premeiotic or early meiotic (leptotene) spermatocytes should not be increased or decreased after pachytene spermatocyte depletion. Indeed, at 11.6 d after the first HU injection, there was no increase in the numbers of tubules containing premeiotic (preleptotene) spermatocytes or decrease in the numbers of tubules containing early meiotic (leptotene) spermatocytes (Fig. 7C and Fig. S8 A, B, E, and F). Similarly, we confirmed that genetic depletion of pachytene spermatocytes, in Dmc1- or Spo11-deficient mice, had no discernible effect on preleptotene or leptotene spermatocytes; in these mutant mice, defects in meiotic progression result in apoptosis of pachytene spermatocytes before or during stage IV (50–53). By contrast, coinjection of WIN18,446 with HU did increase preleptotene spermatocytes and decrease leptotene spermatocytes, and coinjection of RA with HU decreased preleptotene spermatocytes and increased leptotene spermatocytes. These results suggest that meiotic initiation requires RA from sources other than pachytene spermatocytes.

Finally, we tested whether RA from pachytene spermatocytes is required for spermatogonial differentiation, by immunostaining for functional markers of spermatogonial differentiation, STRA8 and KIT (22, 54). As mentioned above, at 11.6 d after the first HU injection, type A spermatogonia in stages VII and VIII of control (Left) or HU-injected (Right) mice, stained with hematoxylin and periodic acid-Schiff (He-PAS). Orange dots, pachytene spermatocytes. (Scale bar: 30 μm.) (E) Quantification of RA levels (pmol/g of testes) in testes of control and HU-injected adult mice. HU + WIN, mice were given injections of HU and then daily injections of WIN18,446, beginning 7.6 d after first HU injection. WIN, mice received daily injections of WIN18,446 for 4 d. Dashed line, limit of detection. ND, not detected (below limit of detection). The far right “WIN” bar graph shows results of two biological replicates. Error bars, mean ± SD, *P < 0.01 (Tukey–Kramer test).

Discussion

RA Regulates Four Key Transitions of Spermatogenesis. We investigated the chemical basis of the exquisite coordination of spermatogenesis, the process by which diploid spermatogonia differentiate into specialized haploid gametes, spermatozoa, at a constant rate. We found that rising levels of an extrinsic signal, RA, regulate four key developmental transitions in mouse spermatogenesis: spermatogonial differentiation and meiotic initiation before meiosis (22) and initiation of spermatid elongation and release of spermatozoa after meiosis (Fig. 8 A). We also found that these pre- and postmeiotic transitions require RA from different cell sources: Sertoli (somatic) cells and pachytene spermatocytes (meiotic cells), respectively (Fig. 8 B). We will now discuss the implications of these findings for understanding the regulation of this temporally and spatially coordinated system of cell division and differentiation (10, 14).

By chemically manipulating the levels of RA in the testes of live animals, we found that RA plays critical, primary roles in the two postmeiotic transitions: initiation of spermatid elongation and release of spermatozoa. Indeed, both of these transitions were inhibited within 2 d after starting injections of a potent inhibitor of RA synthesis, WIN18,446. Conversely, injection of RA was sufficient to induce both of these postmeiotic transitions, again within 2 d. These findings align with, and help explain, prior reports of postmeiotic defects caused by genetic or chemical ablation of RA receptors (RARs) or RA-synthesizing enzymes (23–29). Further, we found that, after meiotic initiation, progression and completion of meiosis and subsequent development of round spermatids are unaffected by manipulations of RA levels, suggesting that RA plays little or no direct role in this middle, 17-d stretch of spermatogenesis. Because RA also coregulates the two premeiotic transitions (17–19, 22), our present findings demonstrate that four of the five generations of spermatogenic cells present in stage VII and VIII tubules undergo transitions regulated by a single extrinsic cue, RA.

It remains to be determined whether RA acts directly on germ cells or indirectly, via Sertoli cells, to regulate the two postmeiotic transitions. RA serves as a ligand to nuclear receptors known as RARs and retinoid X receptors (RXRs), which bind to RA response elements (RAREs) in the regulatory regions of target genes (55). These receptors are expressed specifically in round spermatids in stages VII and VIII (during key transitions) (42), suggesting that RA acts directly on round spermatids to induce their elongation. Indirect RA signaling, via RARs/RXRs in Sertoli cells (42), may also contribute to
Recent studies have addressed the question of whether RA levels fluctuate in the testis to regulate the 8.6-d cycle of spermatogenesis. Insights into the question have emerged from studies of Aldh1a gene expression, RAR receptor function, and relative measurements of RA levels (27, 43, 57). However, the actual concentrations of RA in testes, and their dynamics and range, remained unclear. We previously reported that the RA-responsive marker STRA8 is expressed periodically in the unperturbed testis, and, on this basis, we postulated that RA levels rise and fall periodically (22). By absolute quantification of RA levels, we now provide direct evidence that RA levels change periodically and that these changes are mirrored by changes in STRA8 expression: RA levels are low in stages II to VI, rise in stages VII and VIII, and remain high until stages XII/I. This long elevation of RA levels in stages VII to XII/I is consistent with other published expression data and functional studies (27, 42, 43). By contrast, Hogarth et al. (57) suggested, based on relative RA measurement, a sharp peak in RA levels in stages VIII and IX. This difference between Hogarth et al.’s findings and those reported here likely reflects differences in experimental designs and in methods of measurement and analysis employed. For example, while we analyzed stage-synchronized testes between 5 and 17 d after RA injection, Hogarth et al. analyzed testes between 42 and 50 d after RA injection, by which point synchrony may be less consistent (41, 58).

Our findings demonstrate that, in the unperturbed testis, RA concentrations rise in stages VII and VIII, thereby coordinating four spermatogenic transitions, and they remain elevated until stages XII/I. We previously showed that germ cells have stage-limited competencies to undergo spermatogonial differentiation and meiotic initiation (22). These windows of competence begin while RA levels are low, and end in stage XII/I, where RA levels are still high, so that the competencies intersect with high RA levels briefly to confine the timing of premeiotic transitions (to stages VII and VIII). It remains to be determined whether round spermatids have a similarly limited competency (ending in stage VIII) to undertake the initiation of spermatid elongation (in stages VII and VIII).

**Periodic RA from Sertoli Cells and Pachytene Spermatocytes Coordinates Four Transitions.** Based on the observation that an RA-synthesizing enzyme, Aldh1a2, is expressed in pachytene spermatocytes (42, 43) and that spermatogonial differentiation requires RA, Sugimoto et al. (43) hypothesized that production of RA by pachytene spermatocytes induces the next round of spermatogonial differentiation. Indeed, we found that RA concentrations increase when Aldh1a2-expressing pachytene spermatocytes first appear in young males (Fig. 5 B), consistent with Sugimoto et al.’s suggestion that pachytene spermatocytes produce RA. However, using genetic and chemical cell depletion assays, we showed that RA from pachytene spermatocytes is required for postmeiotic transitions, but not for premeiotic transitions. Based on the findings reported here, we propose that pre- and postmeiotic transitions are regulated by RA from different sources. Specifically, the model posits that Sertoli cells periodically produce RA to regulate two premeiotic transitions and that pachytene spermatocytes produce RA to regulate two postmeiotic transitions. Several observations support the model that these premeiotic transitions are coordinated by RA from Sertoli cells (but not from pachytene spermatocytes). First, Sertoli cell-specific ablations of Aldh1a-3 cause an arrest of the first spermatogonial differentiation in postnatal mice (28). Second, using RA quantification, we now show that RA periodicity (with rising RA concentrations in stages VII and VIII) is maintained even in the absence of pachytene spermatocytes. Further, we provide both chemical and genetic evidence that depletion of pachytene spermatocytes does not affect the timing of the premeiotic transitions: These timed transitions are maintained in Dmc1- and Spo11-deficient males, in which pachytene spermatocytes are

**RA Concentrations Change Periodically, as Reflected by STRA8 Expression Patterns.** Recent studies have addressed the question of whether RA levels fluctuate in the testis to regulate the 8.6-d cycle of spermatogenesis. Insights into the question have emerged from studies of Aldh1a gene expression, RAR receptor function, and relative measurements of RA levels (27, 43, 57). However, the actual concentrations of RA in testes, and their dynamics and range, remained unclear. We previously reported that the RA-responsive marker STRA8 is expressed periodically in the unperturbed testis, and, on this basis, we postulated that RA levels rise and fall periodically (22). By absolute quantification of RA levels, we now provide direct evidence that RA levels change periodically and that these changes are mirrored by changes in STRA8 expression: RA levels are low in stages II to VI, rise in stages VII and VIII, and remain high until stages XII/I. This long elevation of RA levels in stages VII to XII/I is consistent with other published expression data and functional studies (27, 42, 43). By contrast, Hogarth et al. (57) suggested, based on relative RA measurement, a sharp peak in RA levels in stages VIII and IX. This difference between Hogarth et al.’s findings and those reported here likely reflects differences in experimental designs and in methods of measurement and analysis employed. For example, while we analyzed stage-synchronized testes between 5 and 17 d after RA injection, Hogarth et al. analyzed testes between 42 and 50 d after RA injection, by which point synchrony may be less consistent (41, 58).

Our findings demonstrate that, in the unperturbed testis, RA concentrations rise in stages VII and VIII, thereby coordinating four spermatogenic transitions, and they remain elevated until stages XII/I. We previously showed that germ cells have stage-limited competencies to undergo spermatogonial differentiation and meiotic initiation (22). These windows of competence begin while RA levels are low, and end in stage XII/I, where RA levels are still high, so that the competencies intersect with high RA levels briefly to confine the timing of premeiotic transitions (to stages VII and VIII). It remains to be determined whether round spermatids have a similarly limited competency (ending in stage VIII) to undertake the initiation of spermatid elongation (in stages VII and VIII).

**Periodic RA from Sertoli Cells and Pachytene Spermatocytes Coordinates Four Transitions.** Based on the observation that an RA-synthesizing enzyme, Aldh1a2, is expressed in pachytene spermatocytes (42, 43) and that spermatogonial differentiation requires RA, Sugimoto et al. (43) hypothesized that production of RA by pachytene spermatocytes induces the next round of spermatogonial differentiation. Indeed, we found that RA concentrations increase when Aldh1a2-expressing pachytene spermatocytes first appear in young males (Fig. 5 B), consistent with Sugimoto et al.’s suggestion that pachytene spermatocytes produce RA. However, using genetic and chemical cell depletion assays, we showed that RA from pachytene spermatocytes is required for postmeiotic transitions, but not for premeiotic transitions. Based on the findings reported here, we propose that pre- and postmeiotic transitions are regulated by RA from different sources. Specifically, the model posits that Sertoli cells periodically produce RA to regulate two premeiotic transitions and that pachytene spermatocytes produce RA to regulate two postmeiotic transitions. Several observations support the model that these premeiotic transitions are coordinated by RA from Sertoli cells (but not from pachytene spermatocytes). First, Sertoli cell-specific ablations of Aldh1a-3 cause an arrest of the first spermatogonial differentiation in postnatal mice (28). Second, using RA quantification, we now show that RA periodicity (with rising RA concentrations in stages VII and VIII) is maintained even in the absence of pachytene spermatocytes. Further, we provide both chemical and genetic evidence that depletion of pachytene spermatocytes does not affect the timing of the premeiotic transitions: These timed transitions are maintained in Dmc1- and Spo11-deficient males, in which pachytene spermatocytes are
depleted. Finally, Sertoli cells establish a stage-dependent cycle of metabolism in neonatal males, before pachytene spermatocytes first appear (59), leading us to propose that Sertoli cells may produce RA periodically to coordinate the premeiotic transitions, independent of RA from pachytene spermatocytes.

We do not yet know why the pre- and postmeiotic transitions require different cellular sources of RA. In the seminiferous tubules, premeiotic germ cells are confined to the basal compartment, which is separated from the luminal compartment, where pachytene spermatocytes and postmeiotic germ cells are located, by tight junctions formed between Sertoli cells (60) (Fig. 8B). This basal vs. luminal arrangement may influence the diffusion, degradation, and availability of RA produced by Sertoli cells and pachytene spermatocytes. However, we surmise that RA is not segregated strictly between basal and luminal compartments. Indeed, in Sertoli cell-specific Aldh1a1−/−deficient testes, the resulting arrest at the first (juvenile) spermatogonial differentiation could be rescued by a single injection of RA, with all germ cell layers observed subsequently, in adult testes (28). This suggests that RA from pachytene spermatocytes can diffuse into the basal compartment to affect the two premeiotic transitions, perhaps redundantly with RA from Sertoli cells. Conversely, 20 wk after RA injection, Sertoli cell-specific Aldh1a1−/−deficient males displayed abnormalities in release of spermatocytes (28), suggesting that Sertoli cell production of RA may contribute, modestly, to this process. Thus, pachytene spermatocytes may work collaboratively with Sertoli cells to ensure high RA concentrations throughout the seminiferous tubules. Alternatively, the postmeiotic transitions may simply require a higher level of RA (from Sertoli cells plus pachytene spermatocytes) than the premeiotic transitions.

In summary, we conclude that both Sertoli cells and pachytene spermatocytes produce RA to establish a periodicity of testicular RA levels, which coordinate the four key transitions in spermatogenesis in close physical and temporal proximity. Our findings may have practical implications for in vitro spermatogenesis. Recently, successful spermatogenesis from ES cells to haploid spermatid-like cells was achieved by culturing within gonadal aggregates (61). However, postmeiotic spermatogenesis in vitro (to produce functional spermatozoa) has yet to be achieved. Our findings that haploid spermatids require periodic RA signals to complete spermatogenesis may help advance the technology of in vitro gamete production.

**Materials and Methods**

**Mice.** Three types of mice were used: WT (C57BL/6NTac), Dmc1−/−deficient (B6. Cg-Dmc1tm1Jcs/Jcs) (50), and Spoo7−/−deficient (B6-129X1 Spo11tm1Jcs/Jcs) (52). See SI Materials and Methods for strain and genotyping details. Unless otherwise noted, experiments were performed on 6- to 8-wk-old male mice, fed a regular (vitamin A-sufficient) diet. All experiments involving mice were approved by the Committee on Animal Care at the Massachusetts Institute of Technology.

**Statistics.** Unless otherwise noted, data are represented as mean ± SD or SE of three or more biological replicates. When comparing two groups, the t test (one-tailed as indicated) was employed. When comparing three or more groups, a one-way ANOVA with the Tukey-Kramer post hoc test was used.

**Histology.** Testes were fixed overnight in Bouin’s solution, embedded in paraffin, and sectioned at 5 μm thickness. Slides were dewaxed, rehydrated, and heated in 10 mM sodium citrate buffer (pH 6.0). Sections were blocked, incubated with the primary antibody, washed with PBS, and incubated with secondary antibody. Detection was fluorescent or colorimetric. See SI Materials and Methods for details.

**Nuclear Spreads of Spermatocytes.** Testes were dissected to obtain single cells, including spermatocytes, as previously described (8). Cell suspensions were placed on slides and fixed in 1% (vol/vol) PFA. Slides were washed, air dried, and stored at −80 °C before use. For immunostaining, slides were brought to room temperature and washed with PBS. See SI Materials and Methods for details.

**Single-Molecule Fluorescent in Situ Hybridization.** Probe design, synthesis, and coupling were as previously described (47, 63). Testes were fixed in 4% (vol/vol) PFA and embedded in optimal cutting temperature compound (O.C.T.). Frozen blocks were sectioned at 8 μm thickness and dehydrated overnight in 70% (vol/vol) ethanol at 4 °C. Hybridization was performed as previously described (47, 63). Counting of individual mRNA particles, image stitching, and data analysis were performed using custom Matlab software as previously described (47, 63). See SI Materials and Methods for details.

**Absolute Quantification of RA Levels.** Sample preparation and RA quantification were performed according to a published protocol (64). Testes were collected and homogenized by hand in ground glass homogenizers on ice in 1 mL of saline (0.9% NaCl). All-trans RA was extracted and quantified by liquid chromatography/mass spectrometry. See SI Materials and Methods for details.

**ACKNOWLEDGMENTS.** We thank M. Handel (The Jackson Laboratory) for anti-H1t antisera; M. Kane (University of Maryland) and R. Kang (University of Texas MD Anderson Cancer Center) for helpful suggestions; R. Besada, M. Goodheart, K. Igarashi, T. Kunchek, and Y. Soh for experimental support; and K. Romer, J. Hughes, M. Kojima, M. Mikedis, and P. Nicholls for helpful discussions and critical reading of the manuscript. This work was supported by the Howard Hughes Medical Institute and United States Department of Defense Peer-Reviewed Medical Research Program W81XWH-15-1-0337 (to E.F.).
