Apicomplexan pathogens are obligate intracellular parasites. To enter cells, they must bind with high affinity to host cell receptors and then uncouple these interactions to complete invasion. Merozoites of Plasmodium falciparum, the parasite responsible for the most dangerous form of malaria, invade erythrocytes using a family of adhesins called Duffy binding ligand-erythrocyte binding proteins (DBL-EBPs). The best-characterized P. falciparum DBL-EBP is erythrocyte binding antigen 175 (EBA-175), which binds erythrocyte surface glycoporphin A. We report that EBA-175 is shed from the merozoite at around the point of invasion. Shedding occurs by proteolytic cleavage within the transmembrane domain (TMD) at a site that is conserved across the DBL-EBP family. We show that EBA-175 is cleaved by PfROM4, a rhomboid protease that localizes to the merozoite plasma membrane, but not by other rhomboids tested. Mutations within the EBA-175 TMD that abolish cleavage by PfROM4 prevent parasite growth. Our results identify a crucial role for intramembrane proteolysis in the life cycle of this pathogen.

Sim et al., 1994; Tolia et al., 2005). Although some *P. falciparum* strains use predominantly this interaction for invasion, others (including many field isolates) do not, invading through alternative pathways (Dolan et al., 1990; Okoyeh et al., 1999) that use other members of the DBL-EBP family (Duraisingh et al., 2003; Gilberger et al., 2003b). There is extensive redundancy in invasion pathways, and the variety of DBL-EBP paralogues expressed by *P. falciparum* together with polymorphism within them may allow the parasite to evade immune responses and to invade a range of host cells despite widespread polymorphism in human erythrocyte surface molecules (Maier et al., 2003; Mayer et al., 2004). The structural and antigenic diversity across the DBL-EBP family poses hurdles for the development of vaccines or drugs that target these important ligands.

Invasion by all Apicomplexa is accompanied by extensive proteolysis of surface and microneme proteins. During invasion by *P. falciparum* merozoites, both the MSP1 complex and AMA1 are quantitatively shed by cleavage at juxtamembrane sites. The enzyme responsible is a subtilisin-like “sheddase” called PfSUB2 that translocates across the parasite surface (Howell et al., 2003; Harris et al., 2005). A distinct mode of shedding has been observed in the related apicomplexan *Toxoplasma gondii*. Here, several transmembrane microneme proteins that translocate across the parasite through interactions with a subplasmalemmal actinomyosin motor are shed in the final stages of invasion by cleavage within their TMD (Opitz et al., 2002; Zhou et al., 2004). This “capping proteolysis” is mediated by an enzyme, initially dubbed microneme processing protease 1 (MPP1; Carruthers et al., 2000), that is now thought to be a rhomboid, a class of polytopic membrane serine proteases that cleave within the TMD of their substrates (Urban et al., 2001; Urban and Freeman, 2003; Zhou et al., 2004; Brossier et al., 2005; Dowse et al., 2005). All the proteins shed by PfSUB2 and MPP1 have demonstrated or putative binding activity, and the fact that interventions that prevent shedding also inhibit invasion suggests that shedding is required to disengage binding interactions between the parasite and host cell surface, enabling rapid entry into the parasitophorous vacuole (Carruthers and Blackman, 2005). It has not been established whether intramembrane proteolysis plays a role in the release of *Plasmodium* adhesins.

EBA-175 and all other known DBL-EBPs accumulate in soluble form in culture supernatants (Orlandi et al., 1990; Reed et al., 2000; Gilberger et al., 2003b), suggesting that their role at invasion may culminate in their being shed in a manner similar to the adhesins described above. The significance of DBL-EBP shedding has not been investigated. Here, we address this issue. We show that EBA-175 is secreted onto the surface of *P. falciparum* merozoites and is shed at or around the point of invasion. Shedding occurs by cleavage within the TMD at a site that is conserved in all DBL-EBPs. Cleavage is mediated by a rhomboid

---

Figure 1. **EBA-175 is shed at or around the point of erythrocyte invasion and retains region VI.** (A) Schematic of EBA-175 structure, indicating signal sequence (SS), F1 and F2 DBL domains, TMD, and cytoplasmic domain (CYT). The position of region VI is shown, with a Coomassie blue-stained SDS-PAGE gel of purified recombinant region VI (inset). (B) Western blot of 3D7 schizonts, merozoites, and culture supernatant, run on nonreducing 7.5% SDS-PAGE and probed with anti–region VI antibodies. Shed EBA-175 (arrow) migrates more rapidly than the parasite forms. Molecular mass markers are indicated. (C) IFA images of an acetone-fixed segmented 3D7 schizont and free merozoites dual labeled after fixation with mAb 1E1 (anti-MSP119; red) and anti–region VI antibodies (green). The punctate, apical pattern obtained with the latter is typical of microneme staining. (D) EBA-175 is discharged onto the apical surface of free merozoites. Merozoites released from 3D7 schizonts in the presence of anti–region VI antibodies were washed, fixed, and probed with FITC anti-mouse IgG to detect bound anti–region VI antibodies (green), followed by mAb 1E1 (anti-MSP119; red). Many free merozoites exhibit a strong apical FITC signal (thin arrows), whereas residual intact schizonts containing merozoites that were not accessible to the anti–region VI antibodies show only background FITC labeling (thick arrows). No signal was associated with merozoites released in the presence of preimmune mouse antisera (unpublished data). (E) IFA images of newly invaded (=3-h-old) ring-stage 3D7 parasites probed with anti–region VI antibodies after acetone fixation. Most rings did not react at all with the antibodies. Nuclei were stained with DAPI (blue). Identical results were obtained with the W2mef clone (unpublished data). Bars, 5 μm.
called PIROM4 that is expressed at the merozoite plasma membrane but not by other rhomboids tested. Importantly, parasite lines carrying mutations that prevent PIROM4-mediated cleavage could not be established, suggesting that shedding of EBA-175 is important for successful invasion. Our results show that intramembrane proteolysis by PIROM4 is critical to maintenance of the parasite life cycle and suggest that targeting PIROM4 activity may provide a means to interfere with the function of the entire DBL-EBP family.

**Results**

**EBA-175 is shed from the merozoite at or around the point of erythrocyte invasion**

Antibodies raised against a folded, recombinant form of EBA-175 region VI (Fig. 1 A) were specific for schizont and merozoite-derived EBA-175 on Western blots and also reacted with the shed form in culture supernatants (Fig. 1 B). The shed protein therefore retains some or all of region VI, as previously suggested (Kaneko et al., 2000; Duraisingh et al., 2003). The antibodies produced a strong punctate immunofluorescence assay (IFA) pattern in acetone-fixed schizonts and free merozoites, consistent with the micronemal location of EBA-175 (Fig. 1 C). They also reacted specifically with the apical surface of many nonpermeabilized free merozoites, suggesting that EBA-175 is secreted onto the merozoite surface just before invasion (Fig. 1 D). In contrast, the anti–region VI antibodies did not react at all with most newly invaded rings of either the W2mef or 3D7 *P. falciparum* clones, labeling only a small fraction with a weak, punctate pattern (Fig. 1 E and Table I, second column). To examine this in more detail, we took advantage of the fact that parasite lines vary in their degree of dependence on EBA-175 as an invasion ligand. W2mef relies predominantly on sialic acid–dependent pathways for invasion and uses EBA-175 as its dominant invasion ligand, whereas 3D7 is capable of invading into neuraminidase-treated cells did not alter the proportion of 3D7 rings reactive with the anti–region VI antibodies. Collectively, these results imply that at around the time of invasion, EBA-175 is predominantly shed from the merozoite and that this occurs to the same degree regardless of whether EBA-175 is used as a primary ligand mediating invasion. As EBA-175 plays its role in invasion at the parasite–host interface, shedding presumably takes place from the merozoite surface. The truncated form of EBA-175 that appears in culture supernatants is the product of this.

**EBA-175 is shed by a calcium-independent serine protease distinct from PfSUB2**

To study the mechanism of EBA-175 shedding, we used an assay developed for characterizing the sheddase PfSUB2 (Howell et al., 2003; Harris et al., 2005). Merozoites were incubated at 37°C with a range of test additives, and supernatants were analyzed for the presence of shed proteins. Fig. 2 shows that shedding of EBA-175 was readily detectable, as was shedding of the expected MSP1 and AMA1 fragments. Release of EBA-175 was partially sensitive to PMSF and dichloroisocoumarin, indicating the involvement of a serine protease. However, in contrast to MSP1 and AMA1, EBA-175 shedding was not inhibited by either the calcium chelating agent EGTA or recombinant PfSUB2 prodomain (PfSUB2 PD), a selective inhibitor of PfSUB2 (Harris et al., 2005). These data show that EBA-175 is not shed by PfSUB2 but by a distinct, calcium-independent, serine protease.

![Figure 2. EBA-175 is not shed by PfSUB2 but by a distinct calcium-independent serine protease. Shed EBA-175 and processing fragments of AMA1 (AMA148/44) and MSP1 (MSP133) were detected in merozoite supernatants by Western blot as described in Materials and methods. Supernatants were harvested immediately (start) or after a 1-h incubation at 37°C in buffer alone (no additions) or containing the indicated additives. Isopropanol and DMSO were solvent controls for PMSF and dichloroisocoumarin (DCI), respectively, whereas FT control refers to flow-through from the final step of concentration of purified PfSUB2PD by ultrafiltration (Harris et al., 2005), added to the assay at a dilution similar to that used for PfSUB2 PD. These results were reproducible in three independent experiments. In Western blot analysis (similar to that in Fig. 1 A) the shed EBA-175 produced in these assays comigrated with that from culture supernatants (unpublished data), consistent with it being the result of the same protease activity.](image-url)
EBA-175 is shed by cleavage within its TMD at a rhomboid-like site

Shed EBA-175 can be recovered from culture medium by being bound to erythrocytes and then eluted with high salt (Orlandi et al., 1990). We adapted this approach to purify sufficient EBA-175 for structural analysis. SDS-PAGE of the partially purified fractions revealed a major protein species at ~175 kD (Fig. 3 A). Matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) analysis of in-gel tryptic digests confirmed this as EBA-175, with a MASCOT probability score of 462 (Table S1, available at http://www.jcb.org/cgi/content/full/jcb.200604136/DC1). The most C-terminal peptide identified in these digests corresponds to \textit{1406EFDDPSYTCFRK~1427}, which lies just upstream of the TMD (Fig. 3 B). No anomalous peptides were identified that might represent the N- or C-terminal end of the protein, so further samples were digested with Asp-N in the presence of 50% (vol/vol) \textit{18}O water. Under these conditions, products of digestion incorporate both \textit{18}O and \textit{16}O at their C terminus as a result of proteolytic hydrolysis, whereas any peptide derived from the extreme C terminus of the protein substrate should retain a normal \textit{16}O isotope spectrum (Howell et al., 2003, 2005). Examination of these digests by MALDI-TOF again identified only peptides derived from the EBA-175 ectodomain (MASCOT probability score 199), including a region VI–derived ion at \textit{1740.716}, matching 1395DEEYNYC-1407 (calculated \textit{m/z} 1740.717). As expected, all peptides identified with an N-terminal Asp and ending at a residue adjacent to an Asp-N cleavage site exhibited an \textit{18}O-containing spectrum. Within the anomalous peptides observed were only two unlabeled ions that could be assigned as being products of EBA-175 digestion: one at \textit{m/z} 2435.242, corresponding closely to the EBA-175–derived peptide 1408D D P S Y T C F R K E A F S S M P Y Y A 1427 (calculated \textit{m/z} 2435.032; Fig. 3, B and C), and a second, less intense ion at \textit{m/z} 2451.262, matching its expected Met oxidized form (calculated \textit{m/z} 2451.032; unpublished data). The absence of an Asp-N cleavage site at the C terminus of this peptide, together with the absence of \textit{18}O label, implicated it as the C terminus of the shed EBA-175. Collision-induced fragmentation in a nanospray mass spectrometer (Fig. 3 D) confirmed its identity and clearly detected the C-terminal sequence Y-A.

These data map the C terminus of shed EBA-175 to an Ala residue that lies three residues into the TMD. Importantly, potential rhomboid recognition sites within the TMD are underlined, and the conserved Ala at which EBA-175 is cleaved is boxed. (C) MALDI-TOF spectra of EBA-175 Asp-N digests performed in 100% H\textit{16}O or 50% (vol/vol) H\textit{18}O. The peak matching \textit{1406DPSSYTCFRKAEFDMPYYA~1427} [arrow; shown magnified in inset, with observed \textit{m/z} value] is not \textit{18}O-labeled in the lower spectrum, indicating that it derives from the C terminus. For comparison, peaks corresponding to \textit{2272DRNSSNGHHNKENYCN~2287} [calculated \textit{m/z} 2812.493] are indicated as examples of species that in the lower spectrum exhibit the \textit{18}O-labeled isotopic pattern typical of internal peptides. (D) Collision-induced fragmentation spectrum of the unlabeled \textit{m/z} 2435.242 peptide in Asp-N digests. The indicated fragment peaks can be assigned to a \textit{b} and \textit{y} series of ions, with the \textit{b18} and \textit{b19} ions assigning the C-terminal peptide sequence YA. The remaining major ions are all consistent with the indicated sequence.
this Ala is conserved across the DBL-EBP family (Fig. 3 B; Carruthers and Blackman, 2005). Of the few proteases that can hydrolyze intramembrane substrates, only rhomboids cleave close to the luminal side of the TMD; also, cleavage after an Ala is a hallmark of rhomboids (Urban and Freeman, 2003; Zhou et al., 2004; Howell et al., 2005). Collectively, our data show that EBA-175 is shed by a protease with the characteristics of a rhomboid.

The merozoite rhomboid PfiROM1 localizes exclusively to micronemes

Apicomplexan parasites possess several rhomboid-like genes (Dowse and Soldati, 2005). T. gondii has six, of which three (encoding TgROM1, -4, and -5) are expressed in tachyzoites in locations where they might play a role in invasion; TgROM1 is micronemal, whereas the other two larger rhomboids are expressed at the parasite plasma membrane (Brossier et al., 2005; Dowse et al., 2005). Based on these expression patterns, the best candidates for the protease mediating shedding of EBA-175 were considered to be PfiROM1, the P. falciparum orthologue of TgROM1, and PfiROM4, the single orthologue of TgROM4 and -5. Microarray studies have shown that both pfrom1 (PlasmoDB ID PF11_0150) and pfrom4 (PFE0340c) are expressed in P. falciparum blood stages (Bozdech et al., 2003; Le Roch et al., 2003) The predominantly intramembrane nature of rhomboids can make them poor antigens; therefore, to localize these gene products, we attempted to epitope tag the genes using single-crossover homologous recombination. For PfiROM1, we transfected parasites with a plasmid containing a targeting sequence that included pfrom1 coding sequence fused to three copies of the HA epitope (HA3; Fig. S2 A, available at http://www.jcb.org/cgi/content/full/jcb.200604136/DC1). Drug-selected parasites (called 3D7HAROM1HA) were cloned for further characterization. Southern blot (Fig. S2 B) and PCR analysis (unpublished data) confirmed that the plasmid had integrated through the expected recombination event, placing the HA3 tag at the 3′ end of the pfrom1 gene.

Western blot of the clones (Fig. S3 A, available at http://www.jcb.org/cgi/content/full/jcb.200604136/DC1) revealed an anti-HA–reactive protein matching the predicted mass (26.7 kD) of HA-tagged PfiROM1. Schizonts probed with mAb 3F10 showed a punctate IFA pattern that colocalized with the microneme protein AMA1 (Fig. S3 B), indicating that, like its T. gondii homologue, PfiROM1 is a microneme protein. IFA of free merozoites and ring stages showed that, unlike AMA1, which redistributes onto the merozoite surface just before invasion (Howell et al., 2003), PfiROM1 remains exclusively in an apical location; it could not be detected at the merozoite surface (Fig. S3, C and D) and did not colocalize with the plasma membrane marker MSP1,19 in rings (Fig. S3 E). Our results show that PfiROM1 is restricted to micronemes, where it is unlikely to play a part in shedding of surface-located EBA-175.

PfiROM4 is a merozoite surface rhomboid

Attempts to epitope tag the 3′ end of the pfrom4 gene using a similar strategy failed (unpublished data), perhaps indicating that modification of the gene at this site is deleterious to the parasite.

In an alternative approach, we transfected parasites with a construct for episomal expression of N-terminal HA3-tagged PfiROM4, under the control of the pfrom4 promoter. Western blot of the resulting parasite line (called 3D7HAROM4synth) revealed expression of a novel, anti-HA–reactive protein of 84 kD, close to the expected mass of HA-tagged PfiROM4 (Fig. 4 A). IFA showed this colocalized with the plasma membrane marker MSP1 in schizonts (Fig. 4 B). Identical results were obtained using the amal 1 promoter to express the gene (unpublished data). These findings indicate that PfiROM4 is expressed at the merozoite plasma membrane, an appropriate location to play a role in shedding of merozoite surface EBA-175.

Figure 4. PfiROM4 is a merozoite plasma membrane protein. [A] Western blot showing extracts of parental 3D7 and 3D7HAROM4synth probed with mAb 3F10 (anti-HA) and polyclonal anti-AMA1 (loading control). The size of the anti-HA–reactive species detected only in 3D7HAROM4synth is close to the predicted mass (90.4 kD) of HA-tagged PfiROM4. [B] IFA of mature nonsegmented (top) and fully segmented (bottom) schizonts of 3D7HAROM4synth, dual labeled with mAb 3F10 (anti-HA; green) and mAb 1E1 (anti-AMA1; red). The DAPI signal (blue) is not included in merged images for clarity. Bar, 5 μm.
strong surface fluorescence when probed without prior fixation with mAb 3F10, indicating expression of the protein in membrane bound form at the cell surface (Fig. 5 B). Western blot with the same mAb detected a major, ~32-kD, and minor, 25-kD, protein in transfected cells. Region VI contains two potential N-glycosylation sites at N1333 and N1401. N-glycosylation is rare or absent in *P. falciparum* (Howell et al., 2003), so one or both of these residues was substituted with Asp, resulting in expressed products EBAregV1gl1 and EBAregVI, respectively. The latter migrated as a single 25-kD species, close to its predicted nonglycosylated mass of 24 kD; it was also equally well expressed at the surface of transfected COS-7 cells (Fig. 5 B).

Cells were then cotransfected with constructs designed for expression of either wild-type PIROM4 or a mutant form with the predicted active-site Ser residue replaced with Ala, and medium from the cells was examined by Western blot for the appearance of shed forms of the HA-tagged region VI. Coexpression with wild-type PIROM4 resulted in the appearance of shed forms in cell supernatants of anti-HA–reactive proteins that migrated on SDS-PAGE more rapidly than the forms in cell extracts expressing products EBAregV1gl1 and EBAregVI, respectively. The latter migrated as a single 25-kD species, close to its predicted nonglycosylated mass of 24 kD; it was also equally well expressed at the surface of transfected COS-7 cells (Fig. 5 B).

Cells were then cotransfected with constructs designed for expression of either wild-type PIROM4 or a mutant form with the predicted active-site Ser residue replaced with Ala, and medium from the cells was examined by Western blot for the appearance of shed forms of the HA-tagged region VI. Coexpression with wild-type PIROM4 resulted in the appearance of shed forms in cell supernatants of anti-HA–reactive proteins that migrated on SDS-PAGE more rapidly than the forms in cell extracts (Fig. 5 C). Importantly, levels of these shed forms were significantly lower, and not above background levels (unpublished data), when coexpressed with the mutant PIROM4. These results suggested that the shed protein is a result of PIROM4 proteolytic activity.

All DBL-EBP possess a GA or GG motif just proximal to the extracellular side of their TMD (Fig. 3 B), reminiscent of the helixdestabilizing structures that determine sensitivity to rhomboids (Urban and Freeman, 2003). To explore the requirements for recognition of the EBA-175 TMD by PIROM4, three further forms of EBAbregVI with mutations in the TMD were evaluated in the COS-7 cell system (Fig. 5). Substitution of the helix-destabilizing structures that determine sensitivity to rhomboids (Urban and Freeman, 2003). To explore the requirements for recognition of the EBA-175 TMD by PIROM4, three further forms of EBAbregVI with mutations in the TMD were evaluated in the COS-7 cell system (Fig. 5). Substitution of

Figure 5. EBA-175 is a substrate for PIROM4. (A) Structure of EBA-175 minigenes expressed in COS-7 cells. Partial amino acid sequences of the various mutants are indicated. Substitutions made to remove Nglycosylation sites or to modify the TMD (shaded) are in bold and underlined. The position mapped as the site of the EBA-175 shedding is indicated by an arrow. The predicted topology of the expression product is shown (inset). (B) IFA showing expression of EBA-175 minigene products at the surface of COS-7 cells. Cells transfected with the various constructs were probed without fixation or permeabilization with the anti-HA mAb 3F10 (green). In all cases, 15–20% of cells exhibited strong surface fluorescence. Nuclei were stained with DAPI (blue). Bar, 50 μm. (C) Western blots of cells or medium from COS-7 cells cotransfected with EBA-175 minigene constructs and HA-tagged PIROM4 expression constructs, either in wild-type (wt) or mutant (mut) forms. Blots were probed with mAb 3F10. The uppermost band visible in the cell extract blot (arrow) corresponds to HA-tagged PIROM4; note its absence from the farthest right lane, where no PIROM4 construct was transfected. The band just below this is a nonspecific reaction signal. These results were reproducible in >19 independent experiments.

PfROM4-mediated shedding of EBA-175 is critical to maintenance of the *P. falciparum* blood-stage life cycle

To directly address the importance of EBA-175 shedding in the erythrocytic life cycle of *P. falciparum*, we attempted to generate transgenic parasites expressing mutant forms of EBA-175 that lacked one or other of the two TMD GA motifs examined in the previous section. To do this, we constructed plasmids (pHH1-175-GA/F and pHH1-175-GA2/FF) designed to introduce the desired substitutions by recombination into the 3′ end of the *eba-175* gene (Fig. 6 A).
Each plasmid was first transfected into W2mef, and the resulting parasite lines (called EBA175GA/FF and EBA175GA/FF) were drug cycled to select for integrants. Southern blot analysis of EBA175GA/FF revealed a hybridization profile consistent with integration into the eba-175 locus as expected, in the bulk of the parasite population (Fig. 6 B). Confirmation of the expected GA/FF substitution within the eba-175 gene was obtained by PCR amplification (Fig. 6 C) and sequencing (not depicted) of the modified locus. Expression and correct localization of the mutant EBA-175 protein was confirmed by IFA using antibodies against EBA-175 and -181, another micronemal EBL-DBP (Fig. 6 D).

In contrast to the ease with which the EBA175GA/FF transgenic line was derived, establishment of a viable parasite line carrying a substitution of the GA1 motif could not be achieved. In two independent transfection experiments in W2mef and one in 3D7, the input plasmid remained episomal for up to six drug cycles (unpublished data), a typical finding where integration is lethal or severely detrimental to the parasite. Because the two integration constructs used here were identical aside from the few base-pairs within the TMD encoding the mutant codons, it is unlikely that the failure to obtain integration of pH11-175-GA1/FF was a technical problem associated with construct design. Our results support a critical role for the GA1 motif and suggest that modifications that interfere with PiROM4-mediated cleavage of EBA-175 cannot be tolerated by the parasite. Because shedding of EBA-175 occurs at or around the point of erythrocyte invasion, this is likely to be the stage in the life cycle at which arrest occurs after substitution of the GA1 motif.

**Discussion**

Many microneme proteins are secreted onto the parasite surface to play a role in host cell entry and then ultimately shed. This study demonstrates that EBA-175, and, by extrapolation, all other DBL-EBPs, are subject to a similar fate. Given their role in invasion and their capacity to bind erythrocyte surface receptors with high affinity, these ligands presumably function in membrane bound form at the merozoite surface. Our results show that the truncated form of EBA-175 released into supernatants is a result of a physiologically important, precise cleavage event that takes place at the merozoite surface and is mediated via intramembrane cleavage by a rhomboid-like malarial protease.

IFA of newly invaded rings showed that, irrespective of whether EBA-175 was used as the dominant invasion ligand, invasion is associated with shedding of EBA-175. Western blot showed that the shed protein retains much or all of region VI, and mass spectrometric analysis allowed us to map its C terminus to an Ala residue that lies three residues into the predicted TMD, a specificity identical to that of the rhomboid-like cleavage sites previously mapped in apicomplexan microneme proteins (Opitz et al., 2002; Zhou et al., 2004; Howell et al., 2005). We then showed that the P. falciparum homologues of three rhomboids previously localized to the secretory pathway in T. gondii are expressed in merozoites. Whereas PiROM1 was found to be exclusively micronemal, PiROM4 localizes to the merozoite plasma membrane. This is consistent with the findings of Brossier et al. (2005) and Dowse et al. (2005) who showed that EBA-175 is shed by a malarial rhomboid.
showed that TgROM4 and -5, the two T. gondii homologues of PfROM4, are both expressed at the tachyzoite surface. Of these, only TgROM5 showed protease activity against microneme proteins; thus, it was proposed that this is MPP1. Brossier et al. (2005) also found that TgROM5 expression was concentrated at the posterior surface of the tachyzoite, where it may be optimally placed to release transmembrane microneme proteins as they translocate rearwards at invasion. We observed no such bias in the distribution of PfROM4, but our findings do indicate that this rhomboid is expressed at an appropriate time and place to mediate shedding of EBA-175.

Early studies on the protease activity of rhomboids indicated that substrate recognition requires only a suitably disordered TMD resulting from the presence of a helix-disrupting GA or GG motif disposed toward the luminal end of the sequence (Urban and Freeman, 2003). Subsequent studies suggest that this may not be universally true, and there are now indications that structures on the extracellular (Opitz et al., 2002; Brossier et al., 2003; Pascall and Brown, 2004) or intracellular side (Lohi et al., 2004) of the TMD are also important for efficient substrate recognition. The minigene constructs used here to explore cleavage of the EBA-175 TMD incorporated the entire region VI as well as the cytoplasmic domain in anticipation that elements critical for recognition might reside within these juxtamembrane sequences. Of the three rhomboids tested, only PIROM4 cleaved these proteins. Substitution of either the Ala mapped as the site of EBA-175 cleavage, or the GA4 motif, abolished cleavage. The lack of cleavage by either PIROM1 or D. melanogaster Rho-1 shows that these motifs alone are not sufficient to render the EBA-175 TMD susceptible to all rhomboids and implies a degree of specificity in the interaction between PIROM4 and EBA-175. Eukaryotic rhomboids cluster into two major groups referred to as the RHO (typified by D. melanogaster Rho-1) and PARL (typified by the mitochondrial presenilins-associated rhomboid-like protein) subfamilies (Koonin et al., 2003). Both the malarial rhomboids investigated here are more closely related to Rho-1 than to PARL, but PIROM4 differs noticeably from Rho-1 and PIROM1 in possessing unusually large predicted loops between its first and second, and sixth and seventh TMD, as well as extended N- and C-terminal domains (Dowse and Soldati, 2005), structures that may be involved in EBA-175 recognition. Similarly, although region VI is known to be important for the trafficking and structural integrity of EBA-175 (Reed et al., 2000), it might also play a role in recognition by PIROM4.

EBA-175 is the dominant DBL-EBP mediating invasion in the W2mef line, so this isolate was first chosen to examine the effects of TMD mutations that prevent PIROM4-mediated cleavage. Although transgenic parasites lacking the GA2 motif were readily generated, parasites lacking the GA4 motif critical for PIROM4-mediated cleavage could not be. Further work showed that the GA2 mutation could not be introduced into the 3D7 line either. This was initially surprising in view of previous work showing that functional inactivation of EBA-175 by removal of the cytoplasmic tail (Gilberger et al., 2003a) or deletion of the TMD (Reed et al., 2000) can be readily achieved in 3D7 and is easily compensated for in W2mef by a switch to an EBA-175–independent invasion pathway. We accept that caution should be exercised in interpretation of our “negative” result. However, together with our observation that shedding of EBA-175 takes place to the same degree in both parasite lines irrespective of whether the ligand is used for invasion, our results can be reconciled by a model that postulates that if EBA-175 is present in a functional, membrane bound form, it must be capable of being shed for invasion to go to completion. At present we can only speculate on how a defect in shedding could stall invasion. EBA-175 functions as a dimer (Tolia et al., 2005), and if shedding-defective mutants can form heterodimers with other DBL-EBPs, this may exert a dominant-negative effect, interfering with the release of these ligands too from the merozoite surface. EBA-175 is the most abundant DBL-EBP in most P. falciparum isolates examined; thus, an alternative possibility is that a defect in EBA-175 shedding leads to an insurmountable physical barrier at invasion, with an accumulation of unshed EBA-175 preventing the rapid recruitment of other DBL-EBPs to the confined space of the moving junction. It is worth noting that, somewhat analogous to our results, mutations that prevent MPP1-mediated shedding of the T. gondii microneme protein TgMIC6 are deleterious to that parasite, despite the fact that TgMIC6 is not essential for host cell invasion (Opitz et al., 2002).

Could PIROM4 shed merozoite proteins other than the DBL-EBPs? Recent studies have implicated a second family of P. falciparum apical membrane proteins in erythrocyte invasion. Called the reticulocyte binding protein homologues, several lines of evidence indicate an important role, including gene disruption experiments that result in a switch in invasion phenotype (Stubbs et al., 2005). The precise function of these proteins is unclear, but they may have adhesive properties (Rayner et al., 2001), and proteolytic shedding may be important for their function (Triglia et al., 2005). Some members of this family possess helix-disrupting motifs in their TMD, and it will be interesting to determine whether they too can be substrates for PIROM4 or -1.

We have been unable to disrupt the pfrom4 gene by targeted homologous recombination (unpublished data), suggesting that it is indispensable in the blood-stage life cycle of the parasite. Our findings show that erythrocyte invasion involves the activity of at least two serine proteases, PfSUB2 and PIROM4, which have distinct roles and which belong to different protease families. This is consistent with protease inhibitor studies performed over two decades ago indicating that invasion requires the activity of more than one serine protease (Hadley et al., 1983).

Our evidence implicating PIROM4 in invasion by the malaria parasite supports the emerging view that rhomboid-mediated intramembrane proteolysis likely plays multiple roles in biological systems across evolution (Freeman, 2004). Our findings may have important practical implications for antimalarial drug development. P. falciparum has evolved a complex strategy to overcome receptor heterogeneity in its human host, exploiting a diverse family of ligands able to recognize a range of erythrocyte types. The conserved nature of the EBA-175 cleavage site across the DBL-EBP family raises the provocative
notion that all these ligands may share a common requirement to be released at or around the point of invasion by PIROM4-mediated cleavage. Targeting PIROM4 with suitably selective drugs may transcend this ligand diversity, providing a more global approach to blocking invasion than attempting to target the receptor binding function of the ligands themselves.

Materials and methods

Parasite culture and transfection

P. falciparum clones 3D7 and W2meF were cultivated and synchronized as described previously (Blackman, 1994). For invasion assays or production of newly invaded ring stages, schizonts enriched by centrifugation over cushions of 63% Percoll (GE Healthcare) were cultured with fresh erythrocytes for up to 3 h to allow rupture and reinvasion before removal of residual schizonts as described previously (Blackman et al., 1990). For transfection, ring-stage parasites (2–10% parasitaemia) were electrophoretically with 70–100 μg of plasmid DNA using standard procedures (Fidock and Wellemms, 1997). After initial selection for ~4 wk in 2.5 or 10 nM of the antifolate WR99210 (Jacobs Pharmaceutical Co.), parasites were subjected to repeated cycles of selection for 3 wk followed by removal of the drug for 3 wk. Clonal populations were then obtained by limiting dilution.

Antibodies

Recombinant region VI was expressed in the yeast Pichia pastoris. For this, an intronless synthetic gene, called eba175regVI, encoding the C-terminal 170 residues (N1333–K1502) of 3D7 EBA-175 (PlasmodB gene ID PF07_0128) was obtained from GENEART. An N-glycosylation site at N1401 was substituted with Asp using QuikChange site-directed mutagenesis (Stratagene) with primers EBA12for and -rev (see Table S2, available at http://www.ncbi.nlm.nih.gov/GenBank). A second N-glycosylation site at N1444 was modified by the substitution of Thr for Asn (Duez et al., 2005). In brief, 150 μl of packed erythrocytes were washed and re-suspended in 300 μl of protein-free RPMI 1640 supplemented with 1.5 μM NaCl, 10 mM EDTA, and 1 mM PMSF to elute bound protein. Several batches of protein produced in this manner were pooled and then subjected to HiLoad 26/60 Superdex 200 pg gel filtration column equilibrated in 20 mM Tris-HCl, pH 8.0, and 150 mM NaCl. Fractions containing EBA-175 were identified by Western blot. In gel proteolytic digestion of reduced, alkylated protein and peptide analysis by MALDI-TOF and nanospray mass spectrometry was done as described previously (Howell et al., 2003, 2005; Zhou et al., 2004).

Neuraminidase treatment and EBA-175 overlay assays

Erythrocytes were neuraminidase treated as described by Thompson et al. (2001). In brief, 150 μl of packed erythrocytes were washed and re-suspended in 300 μl of protein-free RPMI 1640 25 mM Hepes, pH 6.7, containing 30 μM (30 μl) Vibrio cholerae α2-3,6,8-neuraminidase (Calbiochem), and incubated at 37°C for 2.5 h. Mock-treated cells were incubated similarly without neuraminidase. The cells were washed in culture medium before use in invasion assays. EBA-175 overlay assays were performed as described by Maier et al. (2003). In brief, untreated, mock-treated, or neuraminidase-treated cells were lysed in ice-cold 5 mM sodium phosphate, pH 7.0, and the resulting ghosts were washed extensively in the same buffer before being fractionated by SDS-PAGE on 7.5% gels and transferred to Hybond-C (Stratagene) and blotted with monoclonal antibodies against EBA-175 (Reed et al., 2000) and EBA-181 (Giilberger et al., 2003a).

SDS-PAGE and Western blot

Extracts of parasites, COS-7 cells, medium, and partially purified or purified proteins were subjected to SDS-PAGE under reducing or nonreducing conditions and transferred to Hybond-C extra (GE Healthcare), and membranes were probed with antibodies as described previously (Harris et al., 2005; Pizarro et al., 2005). Binding was revealed by ECL detection (Pierce Chemical Co.).

Merozoite processing assays

Shedding from purified merozoites and the effects of various inhibitors on it was assayed as described previously (Howell et al., 2003; Harris et al., 2005). In brief, 3D7 merozoites suspended in 50 mM Tris-HCl and 5 mM CaCl2, pH 7.6, were divided into equal aliquots of ~4 × 105 merozoites on ice, supplemented with test inhibitors or control buffers, and transferred to 37°C for 1 h. Merozoites were pelleted, and shed proteins were detected in supernatants by Western blot using mAb 4G2, mAb X509, or anti-region VI antibodies.

Indirect immunofluorescence microscopy

Thin films of P. falciparum were fixed with acetone or methanol and processed for IFAs with mAbs as described previously (Harris et al., 2005). For surface labeling of unfixed free merozoites, purified schizonts were cultured for 2 h in medium supplemented with mAb SF10 (1:500) to allow merozoite release. Parasites were then pelleted and washed, thin films were prepared and fixed in acetone, and labeling was continued at the secondary antibody step. For probing with polyclonal antibodies, slides were incubated for 1 h with anti-region VI antisera (1:2,000) or a mixture of rabbit anti-EBA-175 (1:1,000) and mouse anti–EBA-181 (1:1,250) and then washed and incubated for 1 h with FITC-conjugated anti-mouse IgG (1:200, Sigma-Aldrich) or a mixture of Alexa Fluor 594 goat anti-rabbit IgG antibodies (1:2,000) and Alexa Fluor 488 anti-mouse IgG antibodies (1:2,000; Invitrogen) and DAPI (1:1,000, Roche). For IFAs of unfixed COS-7 cells, cells adherent to glass coverslips were transfected and cultured for 48 h and then probed without prior fixation or permeabilization with mAb SF10 (1:500) followed by biotinylated goat anti-rat IgG (1:500; Chemicon) and FITC-conjugated streptavidin (1:500; Vector Laboratories). Samples were mounted in Citifluor (Citifluor Ltd.). Images were captured at 21°C using a Zeiss Axioscope 2. Carl Zeiss Microimaging, Inc.) using a Plan-APORCHROMAT 100×/1.4 (or Plan-APORCHROMAT 63×/1.4 for COS-7 cells) oil-immersion objective, and annotated using Photoshop (Adobe).

Purification of shed EBA-175 and mass spectrometry

Medium harvested from cultures of 3D7 schizonts that had undergone rupture and erythrocyte reinvasion overnight was concentrated 10-fold by ultrafiltration using a 100,000-D molecular mass cutoff membrane (PBHK; Millipore). Human erythrocytes were added to a 5% haematocrit, and the suspension was mixed for 30 min at room temperature to allow binding of EBA-175. The erythrocytes were recovered and resuspended for 10 min in 2 volumes of protein-free RPMI 1640 supplemented with 1.5 M NaCl, 10 mM EDTA, and 1 mM PMSF to elute bound protein. Several batches of protein produced in this manner were pooled and then subjected to 200 pg gel filtration column equilibrated in 20 mM Tris-HCl, pH 8.0, and 150 mM NaCl. Fractions containing EBA-175 were identified by Western blot. In gel proteolytic digestion of reduced, alkylated protein and peptide analysis by MALDI-TOF and nanospray mass spectrometry was done as described previously (Howell et al., 2003, 2005; Zhou et al., 2004).

P. falciparum transfection plasmids

Plasmid pROM1HA for epitope tagging of the pfmod1 gene by homologous recombination was constructed by the insertion of sequence encoding the HA3 epitope, downstream of the pfmod1 coding sequence, into plasmid pH11 (Reed et al., 2000). The HA3 tag was amplified from pREP(HA3)42 (Craven et al., 1998) using primers HAROMtagF and -R and inserted into the EspI and XhoI sites of pHH1 (Reed et al., 2000). The HA3 tag was amplifi ed into pHH1 using Afl II–AvrII sites within the tag. Primers were designed to remove the stop codon from the end of the gene by homo-
control of the pfrmod promoter, the pfrmod 5’ flanking region was amplified from 3D7 gDNA using primers PROMAupf and -R and cloned into the BglII-XhoI sites of pH11. This vector was digested with Xhol and blunt ended, and the HARAM4Δmut fragment was inserted. A 1.4kb NotI Rep20 fragment was included in the final vector, called pHAROM4mut.

The 3’−1 kb of eba-175 was amplified from cDNA using primers EBA175-S54A and EBA175-AS. Mutagenesis of this fragment was achieved in a two-step primer-directed PCR method with Vent polymerase (Stratagene). Substitution of codons encoding 1428GA1429 (GA1) and 1440GA1441 (GA2) with phenylalanine codons was achieved using primer pairs EBA175GA1/FF-S and EBA175GA1/FF-AS or EBA175GA2/FF-S and EBA175GA2/FF-AS, respectively. PCR products were sequenced to confirm the absence of undesired mutations, digested with BamHI and XhoI, and cloned into BglII-XhoI-digested pH11 to produce constructs pH11-175GA1/FF and pH11-175GA2/FF.

Nucleic acid analysis
For Southern blot analysis, gDNA was extracted from parasites as described previously (Harris et al., 2003), restricted and electrophoresed on 0.6% agarose gel, and transferred to Hybond N+ nylon membrane (GE Healthcare) by standard procedures. Probe preparation and Southern blotting was performed using the PrimeIt II random primer labeling kit (Stratagene).

Rhomboid cleavage assay
Sequence encoding HA3 was PCR amplified from pREP[HA3]424 using primers pSceHA4fl and -rev. The product was digested with EcoRI and ligated into pSceCag2a (Invitrogen) that had been digested with SfiI, blunted with T4 polymerase, and further digested with EcoRI. The resulting construct was digested with EcoRI-XhoI and ligated to similarly digested eba175regWV1 to produce expression vector pSCEBAregVlg2. Mutagenesis to remove Nglycosylation sites at N1333 and N1401 and to substitute codons for TMD residues A1427, 1428GA1429, and 1440GA1441 was achieved using QuikChange mutagenesis (Stratagene) using primer pairs EBAam13for and -rev, EBAam12for and -rev, EBAactivator1 and -rev1, EBA1mutf0r1 and -rev1, and EBA1mutf0r2 and -rev2, respectively.

Constructs based on pcDNA3.1 (Invitrogen) for transient expression were amplified from the cDNA library with T4 polymerase, and further digested with EcoRI. The resulting construct was ligated into pSceCag2a and transfected into COS7 cells. Western blot analysis was performed with antibodies raised against the recombinant proteins. Western blot analysis was performed with the following antibodies: mAb 3F10, mAb 5A1, mAb 4C11, and mAb 4G8.

Online supplemental material
Fig. S1 shows that neuraminidase treatment of erythrocytes abolishes EBA-175 binding. Fig. S2 shows generation of a transgenic P. falciparum line expressing HA-tagged PfROM1. Fig. S3 demonstrates that PfROM1 is excluded micronemal. Table S1 lists peptides identified by MALDI-TOF/TOF analysis of PfROM1. All samples were analyzed by Western blot with mAb 3F10.
