Objective Cholinergic nicotinic receptor (CHRN) gene family has been known to mediate the highly additive effects of nicotine in the body, and implicated nicotine dependence (ND) and related phenotypes. Previous studies have found that CHRNA6-CHRNB3 cluster polymorphisms were significantly associated with the risk of ND and various tobacco behaviors. The aim of study was to evaluate the genetic association of CHRNB3 and CHRNA6 polymorphisms with the risk of ND based on the Fagerstrom Test for Nicotine Dependence (FTND) score and five subscales of nicotine dependence syndrome scale (NDSS) in Korean population.

Methods Six SNPs in CHRNA6-CHRNB3 cluster were analyzed in 576 Korean subjects. Association analysis using logistic models and regression analysis with NDSS were performed.

Results There was no association in the case-control analysis, whereas all six SNPs were significantly associated with drive factor among NDSS in subgroup based on the FTND score. CHRNB3 rs4954 and CHRNA6 rs16891604 showed significant associations with NDSSF1 (drive) in dominant models among moderate to severe ND among smokers after correction ($p_{corr}=0.02$ and 0.001, respectively), whereas other four SNPs showed significant associations among mild ND after correction ($p_{corr}=0.03-0.02$ in dominant model).

Conclusion This study showed that the genetic influence of CHRNB3-CHRNA6 cluster polymorphisms are found in a ND endophenotype (drive) using NDSS subscales, rather than the risk of ND in Korean population. Our findings might be the first report for the association of CHRNB3-CHRNA6 cluster with ND-related phenotypes in Korean and might offer an approach to elucidating the molecular mechanisms of ND and ND-related phenotypes.

INTRODUCTION

Cigarette smoking is a major health problem and a leading environmental risk factor for several diseases, such as pulmonary disease and cancer worldwide. Despite the increasing awareness of health-related consequences, a large number of smokers fail to stop smoking due to their nicotine dependence (ND).1 The genetic influences on nicotine dependence were established through twin studies,2-4 and genetic factors with heritability account for between 40–70% of the phenotypic variance.3,4

Cholinergic nicotinic receptor (CHRN) gene family code pentameric molecular assemblies of nicotinic acetylcholine receptor (nAChR) subunits mediate the highly additive effects of nicotine in the body.7 According to the functional importance of nicotinic subunit genes, early genetic association studies of nicotine dependence have been focused on CHRNA4 and CHRNA2,7,8 and the significant associations of the CHRNA5-CHRNA3-CHRNB4 cluster, CHRNB3-CHRNA6 cluster and level of nicotine dependence have been recently reported.9,10 Besides these subunit genes, CHRNB3 and CHRNA5 have emerged as strong candidates for nicotine dependence...
in two recent reports of a genome-wide association and high-
throughput candidate gene survey,\textsuperscript{9,10} and variants in or near \textit{CHRND-CHRNG}, \textit{CHRNA7}, and \textit{CHRNA10} show modest association with nicotine dependence risk in African-Americans.\textsuperscript{11} It has been also suggested that genetic variants in the CHRN gene family are associated with tobacco-related behaviors. \textit{CHRNA5} rs16969968 and rs588765 affect smoking quantity,\textsuperscript{12} and \textit{CHRNA4} variants have been associated with tobacco-related behaviors.\textsuperscript{8,13,14} \textit{CHRNB3} rs4950 and rs13280604 are significantly associated with the subjective response factors to initial tobacco use.\textsuperscript{15} Although studies on smoking and ND based on linkage scans and the candidate gene approach have yielded somewhat inconsistent results,\textsuperscript{16} genetic influences of the CHRN gene family have been replicated in separate community samples and other ethnic populations.\textsuperscript{11,15}

The assessment of ND has relied largely on the use of the Fagerström Tolerance Questionnaire (FTQ) or the Fagerström Test for Nicotine Dependence (FTND).\textsuperscript{17,18} The Fagerström scales were originally developed as unidimensional measures of physical tolerance. There is no assessment of other important aspects of ND, such as craving, subjective compulsion to smoke, nicotine withdrawal, behavioral saliency, or behavioral automaticity, which are now regarded as core constructs. The nicotine dependence syndrome scale (NDSS) was developed using a multidimensional concept of ND, and includes scores on five subscales: Drive, Priority, Tolerance, Continuity, and Stereotypy.\textsuperscript{19}

Previous studies have found that the \textit{CHRNA6-CHRNB3} cluster polymorphisms were significantly associated with the risk of ND and various tobacco behaviors,\textsuperscript{9,10,15,20} and these associations were replicated in a large meta-analysis in samples of European ancestry from the ENGAGE consortium.\textsuperscript{21} To the best of our knowledge, there is no genetic association study of the \textit{CHRNA6-CHRNB3} cluster with the risk of ND and the multidimensional nicotine dependence measure in the Asian population, especially in the Korean population. The aim of the current study was to evaluate the genetic association of \textit{CHRNB3} and \textit{CHRNA6} polymorphisms with the risk of ND based on the FTND score and five subscales of NDSS in the Korean population.

**METHODS**

**Subjects**

Nicotine-dependent patients in several community mental health centers and hospital nicotine dependence clinics were recruited. All (n=371) were diagnosed using the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) criteria. The population controls (n=205) consisted of randomly selected students from Eulji University and Ulsan University of Korea. After a detailed explanation about the process of this study, informed consent was obtained. The Institutional Review Board of the hospital had approved the study. Clinical data from the K-NDSS tests (Korean version of NDSS) were obtained. The clinical profiles of the study subjects were summarized in Table 1.

**SNP selection and genotyping**

Candidate SNPs were selected using the database in the Asian population from the International HapMap Project database (http://hapmap.ncbi.nlm.nih.gov). SNP selection was based on the following criteria: In the 80-kb region including the \textit{CHRNB3} and \textit{CHRNA6} genes, SNPs were selected taking into consideration their minor allele frequencies (MAFs; $\geq 5\%$) and linkage disequilibrium (LD) (only one SNP if there were in absolute; $r^2 \geq 0.95$).

For genotyping of the polymorphic sites, the amplifying primers and probes were designed for TaqMan (Supplementary Table 1, online). The PCRs were run on a TaqMan Universal Master Mix without UNG (Applied Biosystems, Foster City, CA). The amplification cycle parameters were as follows: 95°C for 10 min, 40 cycles of 95°C for 15 s, and 60°C for 1 min. The genotypes were determined using the ABI 7900 HT Real-Time PCR System (Applied Biosystems).

RESULTS

In this study, we examined the association of polymorphisms
in the CHRN3 and CHRNA6 gene region with the risk of
nicotine dependence in Korean subjects (n=576). Asian gen-
type information on 72 SNPs in about 80 kb regions of the
CHRNB3 and CHRNA6 gene were extracted from the Inter-
national HapMap database, and six SNPs were finally selected,
and then genotyped in 371 smokers and 205 non-smokers.
The minor allele frequency and Hardy-Weinberg equilibrium
are summarized in the Supplementary Table 2 (online). Link-
age disequilibria among SNPs were measured by calculating
Lewontin’s D’ and r² values (Supplementary Figure 1, online),
and rs13280604, rs1689161, rs9298628 and rs10109040 were
tightly linked with one another. The haplotypes were con-
structed using six SNPs and only one haplotype (ht1) among
three major haplotypes was used for further analyses because
ht2 and ht3 were almost equivalent to rs16891604 and rs4954,
respectively.

Initially, when the association analysis of six SNPs and a
haplotype were examined using logistic regression models be-
tween smokers and non-smokers, no association was observed
(Table 2). The genetic effects of polymorphisms on the five
subscale factors of NDSS were analyzed using regression mod-
els. CHRNA3 rs4954 and CHRNA6 rs16891604 showed sig-
nificant associations with NDSSF1 (drive) in dominant mod-
els among moderate-to-severe ND among smokers after
correction (p_corr=0.02 and 0.001, respectively) (Table 3), whereas
the other four SNPs were significantly associated with NDSSF1
among mild ND after correction (p_corr=0.04–0.03 in the co-
dominant model and p_corr=0.02 in the dominant model)
(Table 3). Overall associations showed that the drive subscale
of ND was decreased in subjects with minor alleles, but
CHRNB3 rs4954 showed an increase in the drive subscale. In
the additional association analyses for the rest of the NDSSFs,
no association was observed (Supplementary Table 3, online).

Odd ratio and corresponding p-value were calculated by using logistic models whilst controlling by age and sex. NDS: nicotine dependent smoker, NS: non-smoker of population control, CHRN: cholinergic nicotinic receptor, OR: odd ratio, CI: confidence interval.

## Statistical analysis

Haplotypes were inferred using the algorithm developed by the Broad Institute, Haploview.22 We examined Lewontin’s D’ ([D’]) and the linkage disequilibrium coefficient r² between all pairs of biallelic loci.23 The allelic distributions of polymorphisms and haplotypes among patients with nicotine dependence and normal subjects were evaluated by logistic regression models calculating odd ratios (OR), 95% confidence intervals (CI) and corresponding P-values using age and sex as covariates. According to the FTND scores, the gen-
type distributions of patients with severe and mild nicotine dependence were also compared to that of non-smokers. A re-
gression model was used for association analyses with five NDSS subscale factors, adjusting for age and sex as covariates. To correct for multiple testing, the effective number of inde-
dependent markers was calculated using the software SNPSpD (http://genepi.qimr.edu.au/general/daleN/SNPSpD), which is based on the spectral decomposition (SpD) of matrices of pair-wise LD values between SNPs.24 The resulting number of independent marker loci of the CHRN3-CHRNA6 region (3.499) was applied to correct for multiple testing. We ana-
lyzed all the subjects and the dichotomized subgroups; mild
ND (FTND less than 4) and moderate-to-severe (FTND given
4 or more).

DISCUSSION

Drive, which is an essential factor in addiction and one of the NDSS factors, is defined as a presence of craving or withdrawal in the abstinence period. Using the regression analyses of subscales of NDSS among Korean smokers revealed that CHRNB3 and CHRNA6 polymorphisms were significantly associated with the drive subscale factor (Table 3). Interestingly, the genetic associations of four SNPs in CHRNB3 and CHRNA6 polymorphisms were significantly associated with the drive subscale factor (Table 3). Furthermore, the genetic associations of four SNPs in CHRNB3 and CHRNA6 polymorphisms were significantly associated with the drive subscale factor (Table 3). The genetic effects in the dominant model of CHRNB3 rs13280604 and CHRNA6 rs13280604 were opposite from each other, that is, CHRNB3 rs4954 increased the craving of smoking in moderate-to-severe ND subjects but CHRNA6 rs16891604 reduced it. Our results showed that none of the CHRNB3 and CHRNA6 polymorphisms affected the diagnosis of ND; however, CHRNB3 rs4954 and CHRNA6 rs16891604 might play an important role in the craving and withdrawal of smoking in the abstinence period of severe ND subjects, respectively. On the other hand, the rest 4 SNPs of CHRNB3 and CHRNA6, which showed tight linkage with one another, showed the genetic effect for the withdrawal of smoking. These results implicated that the genetic function of CHRNB3-CHRNA6 gene cluster polymorphisms might differ in accordance with the phase of ND. Although CHRNB3 rs4954 also showed the reduced effect of the drive subscale in mild ND, and this effect of CHRNA6 rs16891561 might be due to its low number of subjects with minor homozygote. The limitations of the current study were the low number of subjects and the differences in the male/female ratio and average age between ND smokers and non-smokers. Although these limitations could affect our results by positive or negative false errors, our results might offer a plausible clue of the genetic factors related with ND-related endophenotypes. In fact, the statistical power in the case-control analysis was relatively low (46.70–72.95%) (Table 2), and the additional analysis of the risk of ND in male subjects showed that there was no big difference in the distribution and association results (Supplementary Table 4, online). Several studies have shown that polymorphisms in the CHRNB3-CHRNA6 cluster are associated with the risk of ND and related phenotypes, such as smoking behaviors. CHRNA6...
rs9298629 (absolute LD with rs9298628 in the current study) showed nominal association with the risk of ND in female Israelis. Moreover, SNPs in the 5’ region of CHRNA3 and 3’ UTR of CHRNA6 with the risk of ND were also found in US-based samples and Australian-based European-Ancestry samples. Moreover, CHRNA3 rs4950 and rs13280604 were significantly associated with ND-related phenotypes, such as the subjective responses to nicotine. However, the association of previous studies showed somewhat different results to our results, especially the association results for the risk of ND. The analysis of the MAF and LD structure of 6 polymorphisms among three typical ethnic groups, including Asian, Caucasian and African data from 1000 genome databases (http://browser.1000genomes.org/index.html) revealed that the MAF of CHRNA6 rs16891604 was quite different from that of Caucasians and Africans (Supplementary Table 5, online), and that the LD structures of tested ethnic groups were quite different with one another (Supplementary Figure 2, online). Therefore, our results could be valuable because polymorphisms tested might be specific to ethnic group.

In a study of NDSS using a criterion-group design contrasting chippers and regular smokers, the drive subscale was the most robust correlate of group membership, with an odds ratio of 6.45, accounting for 54% of the variance. The area under the ROC curve for Drive was 0.92, again indicating a very high degree of discrimination. Therefore, the drive subscale may be the most important factor among the subscales of NDSS. Exploring the appropriate phenotype or endophenotype in a genetic study is essential; however, it is difficult to know in advance which phenotype might be associated with specific genes or SNPs. The use of multidimensional scales such as NDSS potentially aids in exploring the construct and nature of ND. In a recent Finnish cohort study, NDSS were used as an ND endophenotype measurement, and it was reported that the tolerance factor of the NDSS showed a suggestive association to CHRN4 rs11634351, and rs1948.

The nicotine dependence phenotype/endophenotype could be various and differ by gender. As mentioned in the limitations, our study did not have an even male/female ratio. In future research, age- and sex-matched genetic analysis is needed.

An a priori assumption of our study was the genetic influences of CHRNA3 and CHRNA6 for the risk of ND as well as ND-related endophenotype. Our results implicated that CHRNA3 and CHRNA6 polymorphisms might be genetic predispositions for the ND-related endophenotypes rather than the risk of ND in the Korean population. To the best of our knowledge, our results may be the first report investigating the association of the CHRNA3-CHRNA6 cluster with ND-related endophenotypes, including subscale factors of NDSS in the Korean population. The current study may be meaningful, although there were several limitations in our study (e.g., the small sample size and smaller portion of females among ND subjects than that of controls).

Conclusion

In conclusion, this study showed that the genetic influence of CHRNA3-CHRNA6 cluster polymorphisms are found in the ND endophenotype (drive) using NDSS subscales, rather than the risk of ND in the Korean population. These effects of multiple loci were different between mild and moderate-to-severe groups of ND. Our findings could offer an approach to elucidating the molecular mechanisms of ND and ND-related phenotypes in the Korean population.

Acknowledgments

This study was supported by a grant of the Ministry of Health and Welfare, Republic of Korea (A0990058).
