SecA mediates cotranslational targeting and translocation of an inner membrane protein

Shuai Wang, Chien-I Yang, and Shu-ou Shan
Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, CA

Protein targeting to the bacterial plasma membrane was generally thought to occur via two major pathways: cotranslational targeting by signal recognition particle (SRP) and posttranslational targeting by SecA and SecB. Recently, SecA was found to also bind ribosomes near the nascent polypeptide exit tunnel, but the function of this SecA–ribosome contact remains unclear. In this study, we show that SecA cotranslationally recognizes the nascent chain of an inner membrane protein, RodZ, with high affinity and specificity. In vitro reconstitution and in vivo targeting assays show that SecA is necessary and sufficient to direct the targeting and translocation of RodZ to the bacterial plasma membrane in an obligatorily cotranslational mechanism. Sequence elements upstream and downstream of the RodZ transmembrane domain dictate nascent polypeptide selection by SecA instead of the SRP machinery. These findings identify a new route for the targeting of inner membrane proteins in bacteria and highlight the diversity of targeting pathways that enables an organism to accommodate diverse nascent proteins.

Introduction

Roughly 30% of the genome encodes membrane proteins, which are anchored to cellular membranes via at least one transmembrane domain (TMD) and play diverse physiological roles such as signaling, cell shape maintenance, and cell motility. To attain their proper structure and function, newly synthesized membrane proteins must engage dedicated protein targeting pathways by which they are delivered to the correct membrane destination in the cell (Zhang and Shan, 2014). Mislocalization of membrane proteins not only deprives cells of functional proteins, but it also disrupts cellular protein homeostasis as a result of improper exposure of the hydrophobic TMDs in the cytosol that could lead to aggregation and misfolding. This demands that the targeting processes for membrane proteins act with high efficiency to minimize the exposure of TMDs in the cytosol.

The cotranslational targeting of proteins by signal recognition particle (SRP) is the most well-understood pathway for targeted delivery of integral membrane proteins. SRP recognizes hydrophobic signal sequences or TMDs near the N terminus of nascent proteins as soon as they emerge from the ribosome exit tunnel (Walter et al., 1981; Schaffitzel et al., 2006; Zhang and Shan, 2014). The TMD on the nascent protein is shielded from the cytosol by the M domain of SRP. Through the interaction between SRP and the SRP receptor (SR; termed FtsY in bacteria), the nascent protein is delivered to the SecYEG (or Sec61p) protein translocation machinery on the bacterial inner membrane (or the eukaryotic endoplasmic reticulum; Zhang et al., 2010). SRP-dependent targeting is complete before ∼130 amino acids of the nascent polypeptide C-terminal to the signal sequence or TMD is translated (Siegel and Walter, 1988; Ariosa et al., 2015), and releasing nascent proteins from the ribosome abolishes the targeting of SRP-dependent substrates (Kuruma et al., 2005). In bacteria, SRP is generally thought to mediate the targeted delivery of the majority of inner membrane proteins and several periplasmic secretory proteins that contain highly hydrophobic signal sequences (Luirink and Sinning, 2004; Schibich et al., 2016).

A second major protein-targeting pathway in bacteria uses SecA, with the participation of the chaperone SecB in some cases. The SecB/A pathway targets the majority of secretory and outer membrane proteins via a posttranslational mechanism (Hartl et al., 1990). Substrates entering this pathway contain signal sequences that are less hydrophobic than those that engage SRP/SR (Neumann-Haefelin et al., 2000). These signal sequences are recognized by the preprotein cross-linking domain of SecA, which couples its ATPase cycle to the translocation of substrate proteins across SecYEG (Bauer et al., 2014). The posttranslational chaperone SecB assists in maintaining preproteins in the unfolded translocation-competent state while also delivering these proteins to SecA bound at the inner membrane (Weiss et al., 1988). The posttranslational nature of the SecB/A pathway is supported by the following observations: (A) classic SecB/A-dependent substrate proteins, such as OmpA and...
PhoA, can be efficiently inserted into the membrane without coupling the targeting reaction to protein synthesis (Hartl et al., 1990; Gouridis et al., 2009), indicating that a cotranslational mode of targeting is not mechanistically obligatory for these substrates; (B) the SecA ATPase cycle and its interaction with SecYEG are enhanced by the mature domain of the nascent protein C-terminal to the signal sequence, suggesting that a substantial length of the nascent protein needs to be exposed before they are targeted by the SecB/A pathway (Gouridis et al., 2009); (C) C-terminal fusion to fast-folding proteins such as thioredoxin (TrxA) severely blocks the translocation of SecA-dependent substrate proteins (Huber et al., 2005a), suggesting that targeting and translocation was not finished before the complete synthesis of the nascent polypeptide.

More recently, however, SecA was found to also interact with the ribosome. SecA binds the 70S bacterial ribosome with a dissociation constant \( K_d \) of 0.9 µM (Huber et al., 2011), in a dissociation constant \( K_d \) with the ribosome. SecA binds the 70S bacterial ribosome with complete synthesis of the nascent polypeptide. thioredoxin (TrxA) severely blocks the translocation of SecA-dependent substrate proteins (Huber et al., 2005a), suggesting that targeting and translocation was not finished before the complete synthesis of the nascent polypeptide.

Up till now, SRP is the only known factor in bacteria that can cotranslationally target inner membrane proteins. Nevertheless, model SRP substrates are still targeted to the bacterial inner membrane, albeit more slowly, under SRP-depleted conditions (Wickström et al., 2011; Zhang et al., 2012), suggesting the presence of alternative targeting pathways for inner membrane proteins. In addition, SecA is required for the insertion of multiple inner membrane proteins that contain large periplasmic domains (Wolfe et al., 1985; Gebert et al., 1988; Säälä et al., 1995; Traxler and Murphy, 1996), which implicates that SecA plays a role at some stage of the biogenesis of these membrane proteins. Moreover, some inner membrane proteins in Escherichia coli depend on SecA rather than SRP for insertion (Ulbrandt et al., 1997; Kihara and Ito, 1998; Rawat et al., 2015). An inner membrane protein, AcrB, showed more severe defects in membrane insertion under SecA-depleted, than SRP-depleted, conditions (Qi and Bernstein, 1999). Recently, Rawat et al. (2015) explored the insertion requirements of two single-span membrane proteins, RodZ and CadC, and suggested the possibility that RodZ is inserted cotranslationally by SecA (Lindner and White, 2014). A common feature of both proteins is a TMD >100 residues downstream of the N terminus and a strict dependence on SecA, but not SRP or FtsY, for insertion. In chloroplasts, cpSecA has been speculated to be an alternative targeting factor, as the cpSecA-dependent substrate protein PetA is cotranslationally targeted to the thylakoid membrane (Zoschke and Barkan, 2015). These observations compel us to explore the possible role of SecA in mediating a potential cotranslational targeting pathway for inner membrane proteins.

Using a combination of quantitative binding measurements, in vitro reconstitutions, and in vivo targeting assays, we demonstrate in this study that SecA cotranslationally recognizes and targets the inner membrane protein RodZ. The extended N-terminal element (NTE) preceding the internal TMD of RodZ and periplasmic sequences immediately after the TMD enable the selection of RodZ by SecA, rather than the SRP machinery, for membrane targeting. This study uncovers a new role of SecA and provides evidence for an SRP-independent cotranslational targeting pathway for a subset of inner membrane proteins in bacteria.

**Results**

**SecA cotranslationally interacts with the RodZ nascent chain**

As a candidate substrate that could cotranslationally interact with and be targeted by SecA, we tested RodZ (Rawat et al., 2015). RodZ is a single-pass type II membrane protein comprised of an N-terminal cytoplasmic domain (residues 1–111), a TMD (residues 112–132) anchored on the bacterial plasma membrane, and a C-terminal periplasmic domain (residues 133–337). The in vivo biogenesis of RodZ was shown to be dependent on SecA and SecYEG but had no dependence on the bacterial SRP protein Ffh, the SR FtsY, or the posttranslational chaperone SecB (Ulbrandt et al., 1997; Rawat et al., 2015). As discussed by Rawat et al. (2015), a cotranslational mechanism of targeting would be beneficial for minimizing the cytosolic exposure of the RodZ-TMD and the premature folding of the RodZ periplasmic domain in the cytosol; we therefore hypothesized that SecA could be recruited to ribosome-nascent chain complexes (RNCs) bearing newly synthesized RodZ.

To detect the interaction between RNC\(_{\text{RodZ}}\) and SecA, we used Förster resonance energy transfer (FRET). As the FRET donor, we used amber suppression technology (Saraogi et al., 2011) to incorporate a fluorescent amino acid, 7-hydroxycoumaryl methylglycine (Cm), at residue 111 upstream of the RodZ N-terminal element (NTE) preceding the internal TMD of RodZ; the RodZ nascent chain is followed by a 34-residue SecM stalling sequence (Nakatogawa and Ito, 2002), which occupies most of the ribosome exit tunnel (Zhang et al., 2015). When purified RNC\(_{\text{RodZ}}\) was incubated with SecA\(_{\text{BDP}}\), we observed a 44% reduction in Cm fluorescence and a corresponding increase in BDP fluorescence, indicating FRET (Fig. 1 B, red). As expected from the competition between labeled and unlabeled SecA, addition of a 10-fold excess of unlabeled SecA completely blocked the FRET signal (Fig. 1 B, blue). This result also ruled out the environmental sensitivity of Cm as a contributor to the FRET signal and indicated a reversible binding equilibrium between RNC\(_{\text{RodZ}}\) and SecA.

Equilibrium titrations based on the FRET assay showed that SecA binds RNC\(_{\text{RodZ}}\) tightly, with a \( K_d \) value of ~1 nM (Fig. 1 C); this affinity is ~900-fold higher than that of SecA for empty ribosomes (Huber et al., 2011), suggesting additional interactions of SecA with the RodZ nascent chain. As other ribosome-associated protein biogenesis factors such as SRP and trigger factor (TF) could compete for binding to the ribosome and RodZ nascent chain under physiological conditions.
SecA mediates cotranslational protein targeting

(Ariosa et al., 2015; Gamerdinger et al., 2015), we further tested whether the SecA–RNC RodZ interaction survives the presence of these factors. Equilibrium titrations in the presence of near-physiological concentrations of SRP (400 nM) or TF (2 µM) showed that the SecA–RNC RodZ interaction was weakened by these factors but remained strong, with $K_d$ values of $\sim 19$ nM and $\sim 55$ nM, respectively (Figs. 1 C and S1 B). In addition, raising the SRP concentration beyond 50 nM did not significantly weaken the binding between SecA and RNC RodZ (Fig. 1, D and F; and Fig. S1 C). As a negative control, we used RNCFtsQ, a well-characterized SRP substrate (Estrozi et al., 2011). Although the interaction of SecA with RNCFtsQ could be detected, this interaction was $\sim 20$-fold weaker than that with RNC RodZ (Fig. 1, E and F), indicating that SecA binds the PhoA nascent chain independently of the ribosome. As a positive control, the interaction of SRP with its substrate, RNC FtsQ, was also disrupted by the RNase A and EDTA treatment (Fig. 2, D and E, blue). However, SRP-RNCFtsQ binding was unaffected by the L23 mutations (Fig. 2, D and E, red), indicating that this acidic patch on L23 provides a specific docking site for SecA. These results show that efficient recruitment of SecA to the RodZ nascent chain requires specific contacts of SecA with the ribosomal protein L23.

SecA recognizes multiple sequence elements on the RodZ nascent chain

To probe the sequence elements on the RodZ nascent chain required for SecA recognition, we first tested the role of the RodZ TMD (Fig. 3 A). Introduction of two arginines weakened the SecA–RodZ interaction $\sim 26$-fold, raising the $K_d$ value to $\sim 26$ nM (Fig. 3 B, TMD mut). Introduction of six basic residues into RodZ-TMD abolished detectable interaction of SecA with the ribosomal protein L23.

We next asked whether the ribosome contributes to the recruitment of SecA onto nascent RodZ. To this end, we disassembled the ribosomes in purified RNCs by RNase A and EDTA treatment (Fig. 1 A). As an independent and more specific means to perturb the SecA–ribosome interaction, we mutated an acidic patch (F51A/E52A/E54A/E56A/E89A) on the ribosomal protein L23 that contacts the N terminus of SecA (Huber et al., 2011; Singh et al., 2014). Both perturbations significantly weakened the interaction of SecA with the RodZ nascent chain. The L23 mutations weakened the binding affinity of SecA for RNC RodZ $>20$-fold (Fig. 2, B and E, red). The binding defect was larger, $\sim 60$-fold, with EDTA- and RNase A–treated RNC RodZ (Fig. 2, B and E, blue). As a negative control, we tested RNC bearing the nascent chain of PhoA, a posttranslational SecA substrate (Gouridis et al., 2009). Although an interaction between SecA and RNCFtsQ could be detected, neither the L23 mutations nor the EDTA–RNase A treatment affected this interaction (Fig. 2, C and E), indicating that SecA binds the PhoA nascent chain independently of the ribosome. As a positive control, the interaction of SRP with its substrate, RNC FtsQ, was also disrupted by the RNase A and EDTA treatment (Fig. 2, D and E, blue). However, SRP-RNCFtsQ binding was unaffected by the L23 mutations (Fig. 2, D and E, red), indicating that this acidic patch on L23 provides a specific docking site for SecA. These results show that efficient recruitment of SecA to the RodZ nascent chain requires specific contacts of SecA with the ribosomal protein L23.
RNCRodZ interaction would be sensitive to the length of the nascent chain. In the hydrophobic TMD on RodZ provides an important recognition by providing multiple simultaneous interactions. The RodZ TMD is preceded by an extended NTE comprised of a helical MreB-binding domain (MBD; residues 1–103) followed by a consecutive sequence of six basic residues (KRRKKR; residues 104–109). Deletion of the MBD did not perturb high-affinity binding between SecA and RNCRodZ, whereas deletion of the basic residues preceding the TMD weakened binding >10-fold (Fig. 3, D–F). These results are consistent with previous findings that positively charged residues N-terminal to the signal sequence enhance preprotein binding and translocation by SecA (Akita et al., 1990; Hikita and Mizushima, 1992).

The enhancement in the RNC binding affinity of SecA when the RodZ nascent chain was lengthened from 140 to 160 amino acids suggests the possibility of additional interactions of SecA with the periplasmic sequence of RodZ after the TMD. To test this hypothesis, we replaced the sequences in the N-terminal periplasmic region of RNCRodZ (residues 134–160) with the corresponding sequence from FtsQ (Fig. 3, D, Peri swap). This mutation weakened the affinity of SecA for RNCRodZ >40-fold (Fig. 3, E and F), indicating that the periplasmic sequence of RodZ after its TMD also contributes significantly to high-affinity SecA recruitment. Intriguingly, this periplasmic region of RodZ does not belong to the “hydrophobic patch” that binds SecA as described by previous studies (Gouridis et al., 2009; Chatzi et al., 2017), but is instead unusually enriched in acidic residues (net charge −4) compared with the corresponding region of FtsQ (net charge 0; Table S1). To test whether these acidic residues contribute to SecA recruitment, we further incorporated the acidic residues in the periplasmic region of SecA into the corresponding positions in the FtsQ periplasmic sequence (R54E/K59E/R66E/H67D/R70D; Fig. 3 D, Peri swap acidic). The incorporation of these additional acidic residues indeed restored high-affinity SecA binding (Fig. 3, E and F, peri swap vs. peri swap acidic), indicating the importance of these acidic residues in SecA recognition.

Finally, to distinguish whether the periplasmic sequence of RodZ exerts its effect directly by interacting with SecA or indirectly by altering the conformation of the remainder of the RodZ nascent chain, we fused this sequence (RodZ residues 134–160) or the corresponding periplasmic sequence from FtsQ (residues 50–74) to the well-folded small ubiquitin-like modifier (SUMO) protein. We tested whether the resulting fusion proteins acted as competitive inhibitors of the interaction between SecA and RNCRodZ. If the periplasmic sequence of RodZ directly bound SecA, SUMO-RodZ(peri) should be able to compete with RNCRodZ for SecA binding and thus restore the fluorescence signal of donor-labeled RNC caused by loss of FRET between RNCRodZ and SecABDP (Fig. 3 G). Dose-dependent saturable restoration of the fluorescence of RNCRodZ was indeed observed with SUMO-RodZ(peri) (Fig. 3 H). In contrast, SUMO by itself did not compete with RNCRodZ and SUMO-FtsQ(peri) provided significantly less effective competition than SUMO-RodZ(peri) (Fig. 3 H). Quantitative analysis of this competition reaction yielded an estimated $K_i$ value of 1.2 µM for the interaction between SecA and SUMO-RodZ(peri).

Collectively, the results in this section show that the strong interaction of RNCRodZ with SecA are contributed by three sequence elements on the RodZ nascent chain: (A) the consecutively positively charged residues upstream of the RodZ TMD, (B) the hydrophobic TMD of RodZ, and (C) the negatively charged residues in the periplasmic region of RodZ after its TMD. It is likely that each of these elements contributes a modest affinity, but together they enable high-avidity SecA recognition by providing multiple simultaneous interactions.
SecA mediates cotranslational protein targeting • Wang et al. 3843

RodZ is cotranslationally targeted and translocated in vivo independently of SRP

The cotranslational recruitment of SecA to nascent RodZ in vitro raised the possibility of SecA-mediated targeting and translocation of RodZ. Previous work showed that the in vivo insertion of RodZ is strictly SecA dependent (Rawat et al., 2015). To further test whether the targeting and translocation of RodZ occurred cotranslationally, we adapted a previously developed in vivo assay based on fusion of the N-terminal targeting sequence (NTS; Fig. 4 A and Table S1) of the protein of interest to TrxA (Schierle et al., 2003; Huber et al., 2005b). TrxA folds rapidly and tightly in the cytosol, which would block its translocation across the membrane if targeting and translocation of the fusion protein occurred after the C-terminal TrxA is fully synthesized. Only if the NTS enables a cotranslational mode of targeting and translocation would TrxA be successfully translocated across the inner membrane (Fig. 4 A), providing an independent readout for their secretion into periplasm. For proteins that contain a TMD anchored in the bacterial inner membrane, successful translocation of TrxA across the inner membrane exposes the Myc tag to the periplasm, where it is susceptible to protease...
K digestion (Fig. 4 A); this provides an independent readout for the proper insertion of the fusion protein at the inner membrane.

When the PhoA signal sequence (residues 1–21; Table S1) was used as the NTS, only a small fraction of the fusion protein was successfully translocated into the periplasm (Fig. 4, B and C), consistent with previous work showing that PhoA is primarily posttranslationally targeted by SecA (Schierle et al., 2003; Gouridis et al., 2009). As previously reported (Schierle et al., 2003), the more hydrophobic signal sequence from DsbA (residues 1–19; Table S1) enabled efficient translocation of TrxA into the periplasm (Fig. 4 B). The N-terminal sequence containing the TMD of FtsQ (residues 1–33; Table S1), a substrate of the cotranslational SRP pathway, directed efficient targeting of the fusion protein to the inner membrane (Fig. 4 B). The C-terminal Myc tag in FtsQ(1–33)-TrxA was susceptible to proteinase K digestion in spheroplasts, indicating that its C terminus was successfully translocated across the bacterial inner membrane (Fig. 4 B). These data validated the robustness of the TrxA-based assay to distinguish co- versus posttranslational modes of targeting and insertion in vivo. Importantly, when RodZ residues 1–150 encompassing its TMD was fused to TrxA (Table S1), the fusion protein was efficiently targeted to and translocated across the bacterial inner membrane analogously to FtsQ (Fig. 4 B), indicating that the RodZ-TrxA fusion protein was cotranslationally targeted and inserted in vivo.

To further test the dependence of the targeting reaction on the SRP protein Ffh, we used the WAM121 strain in which Ffh expression is under control of the ara promoter (de Gier et al., 1996). In contrast to FtsQ, which depends on Ffh for proper insertion to and translocated across the bacterial inner membrane analogously to FtsQ (Fig. 4 B), indicating that the RodZ-TrxA fusion protein was cotranslationally targeted and inserted in vivo.

Figure 4. RodZ is cotranslationally targeted and translocated in vivo. [A] Scheme of the in vivo assay to distinguish between co- and posttranslational modes of targeting and translocation based on NTS-TrxA fusions. All NTS sequences are provided in Table S1. [B, left] Subcellular localization of NTS-TrxA fusion proteins. C, cytosol; M, membrane; PM, periplasm; T, total. [B, right] Assay for translocation of the C terminus of the NTS-TrxA fusion proteins into periplasm based on protection against proteinase K. K, proteinase K; Triton X-100. [C] Controls for cell fractionation. Mature AmpC is secreted into the periplasm (asterisk). YidC is an inner membrane protein. TrxA is a cytoplasmic protein. [D] Effects of Ffh depletion on the targeting and translocation of NTS-TrxA fusions. In vivo targeting and insertion were measured and analyzed as in B. Ffh expression is under control of the arabinose promoter. [E] Ffh is depleted in WAM121 cells grown in glucose without significantly affecting SecA abundance. [F] Translocation efficiency of NTS-TrxA constructs derived from the data in D and their replicates. Asterisks in B–D denote mature translocated secretory proteins whose signal sequences have been cleaved. Values represent mean ± SD; n = 2–3 biological replicates.
Although SecA dependence was observed for the targeting and translocation of all the NTS-TrxA fusion proteins tested in the in vivo assay (Fig. S2 A), these data likely reflect a requirement for SecA during the translocation of the TrxA moiety and cannot be used to conclusively infer the involvement of SecA in their targeting (Schierle et al., 2003). In addition, in vivo experiments could only demonstrate the requirement, but not sufficiency, for specific factors. These limitations were addressed by in vitro reconstitution experiments described in the next section.

SecA provides the minimal factor sufficient to drive the cotranslational targeting and insertion of RodZ in vitro

We sought to reconstitute the targeting and insertion of nascent RodZ using the PURE in vitro translation (IVT) system (Shimizu et al., 2001) coupled with urea-washed inner membrane vesicles (IMVs; U-IMVs; Kuruma et al., 2005); successful translocation of substrate proteins across U-IMVs leads to their partial or complete protection from proteinase K digestion. This homologous IVT translocation system contains no endogenous targeting factors, allowing us to probe the contribution of specific factors to the targeting and translocation of protein substrates of interest.

OmpA is a well-studied outer membrane protein that is posttranslationally targeted and translocated by SecA (Hoffschulte et al., 1994; Kuruma et al., 2005). Consistent with these expectations, proOmpA exhibited SecA-dependent but SRP- and FtsY-independent targeting and translocation across U-IMVs in the IVT translocation assay (Fig. 5 A and replicates in Fig. S3 A). However, FtsQ requires SRP and FtsY for targeting to the membrane and SecA for translocation of its periplasmic loop (Scotti et al., 1999; Kuruma et al., 2005). The coupled IVT translocation assay recapitulated the dependences of FtsQ on both factors (Fig. 5 A and replicates in Fig. S3 A). Importantly, RodZ was inserted in the presence of SecA alone in this assay, and the additional presence of SRP/FtsY did not improve its translocation efficiency (Fig. 5 A and Fig. S3). These data are consistent with the in vivo observation that RodZ requires SecA but not SRP and FtsY for its proper biogenesis (Fig. 4; Ulbrandt et al., 1997; Rawat et al., 2015). Moreover, they strongly suggest that SecA provides the minimal factor that can mediate the targeting and insertion of newly synthesized RodZ.

To test the cotranslational requirement for RodZ insertion in this assay, we changed the order of addition of targeting/translocation components. Robust insertion of RodZ was only observed if SecA and U-IMVs were added during IVT (Figs. 5 B and S3 B, reaction 1). In contrast, if SecA and U-IMVs were added after termination of translation by chloramphenicol, no insertion was observed (Figs. 5 B and S3 B, reaction 3). Under this obligatorily posttranslational condition, proOmpA was still efficiently inserted, albeit with lower efficiency than if SecA and U-IMVs were supplied during IVT (Figs. 5 B and S3 B, reactions 2 vs. 3). Finally, although inclusion of the posttranslational chaperone SecB improved the insertion efficiency of proOmpA as previously described (Kuruma et al., 2005), SecB did not affect the targeting and insertion of RodZ (Figs. 5 B and S3 B, reactions 1 vs. 2; Rawat et al., 2015). Collectively, these results support the model that SecA provides the minimal machinery sufficient for the cotranslational targeting and insertion of RodZ.

The extended NTE and early periplasmic region of RodZ dictate its selection by SecA over SRP

The majority of the bacterial inner membrane proteome is generally thought to be targeted by SRP, which recognizes hydrophobic TMDs or signal sequences on the nascent polypeptide. The observation that SecA also cotranslationally recognizes the RodZ-TMD raises the intriguing question of how nascent membrane proteins are selected between these two factors. Comparison of RodZ with well-studied SRP substrates such as FtsQ suggested the 111-residue NTE of RodZ preceding its TMD...
as a potential distinguishing feature. Another SecA substrate, EspP, was shown to be excluded from the SRP pathway because of its extended NTE, and deletion of this NTE reroutes EspP to the SRP pathway (Peterson et al., 2003; von Loeffelholz et al., 2013). We therefore hypothesized that, analogous to EspP, the extended NTE of RodZ disfavors its engagement with SRP.

To test this hypothesis, we deleted the NTE of RodZ (RodZΔNTE) or fused the RodZ NTE to the N terminus of FtsQ-TMD (RodZNTE-FtsQ; Fig. 6 A and Table S1). We tested the effects of this mutation on multiple activities: (A) the binding affinity of SecA and SRP for RNCs displaying WT and mutant nascent chains (Fig. 6, B and C); (B) the SecA and SRP dependence of preprotein targeting and translocation across U-IMVs in vitro (Fig. 6, D–G); and (C) the SRP dependence of translocation of NTS-TrxA fusion proteins in vivo (Fig. S2, C and D). Deletion of the NTE significantly weakened the binding of SecA and SRP for RNCs displaying WT and mutant TMD (RodZNTE-FtsQ; Fig. 6 A and Table S1). We tested the targeting and translocation across U-IMVs in vitro rather than RodZ (Fig. 6 D). These results are consistent with our earlier finding that the basic residues in the RodZ NTE are important for high-affinity SecA recruitment (Fig. 3 C).

However, deletion of the NTE from RodZ enabled strong SRP binding to the RNC even in the presence of competing SecA and TF (RodZ vs. RodZΔNTE; Fig. 6 C). In agreement with the binding data, deletion of the NTE converted RodZ into an SRP-dependent substrate in the IVT translocation assay in vitro (Fig. 6 E) and increased the SRP dependence of the translocation of RodZ-TrxA fusion proteins in vivo (RodZ vs. RodZΔNTE; Fig. S2, C and D). These data suggest that the NTE of RodZ disfavors SRP binding. As predicted from this hypothesis, fusion of the RodZ NTE to the N terminus of FtsQ TMD destabilized SRP binding to RNC(FtsQ in the presence of SecA and TF (FtsQ vs. RodZNTE-FtsQ; Fig. 6 C, black bars). Consistent with these binding data, fusion to the RodZ NTE also abolished the SRP dependence of FtsQ targeting to U-IMVs in vitro (FtsQ vs. RodZNTE-FtsQ; Fig. 6 G) and reduced the SRP dependence of the targeting and insertion of FtsQ-TrxA in vivo (FtsQ vs. RodZNTE-FtsQ; Fig. S2, C and D). Thus, the N-terminal extension of RodZ is necessary and sufficient to prevent the nascent protein from engaging the SRP-targeting machinery.

However, fusion of the RodZ NTE to the N terminus of FtsQ did not confer tight SecA binding (RodZNTE-FtsQ; Fig. 6 B) nor efficient SecA-dependent targeting into U-IMVs (RodZNTE-FtsQ; Fig. 6 F), indicating that the NTE of RodZ is not sufficient to reroute an SRP substrate to a SecA-dependent pathway. Because the periplasmic region of RodZ after its TMD is also important for high-affinity SecA recognition (Fig. 3), we further replaced the sequences in the FtsQ periplasmic domain after its TMD (residues 50–74) with the corresponding sequence from RodZ (RodZ NTE-peri-FtsQ; Fig. 6 A). RNCs bearing the resulting construct bound tightly to SecA (Fig. 6 B) and displayed SecA-dependent targeting and insertion into U-IMVs in vitro (Fig. 6 F). RodZ NTE-peri-FtsQ did not bind strongly to SRP (Fig. 6 C) nor was it targeted and inserted into U-IMVs in an SRP-dependent manner (Fig. 6 G), indicating that it resembles RodZ as a SecA-dependent and SRP-independent substrate. Thus, the extended NTE together with the early periplasmic region of RodZ are sufficient to reroute an SRP-dependent membrane protein into the alternative SecA-mediated cotranslational targeting pathway.

### Discussion

Protein targeting to the bacterial cytoplasmic membrane was generally thought to occur via two major pathways (Fig. 7). The majority of periplasmic, secretory, and outer membrane proteins contain weakly hydrophobic signal sequences and are targeted posttranslationally with or without the aid of the chaperone SecB to SecA–SecYEG complexes that translocate preproteins across the inner membrane (Fig. 7, left path). Proteins containing TMDs or highly hydrophobic signal sequences near the N terminus are recognized by SRP as soon as they emerge from the ribosome exit tunnel and are delivered cotranslationally to the SecYEG translocation machinery via interaction between SRP and the SecE (Fig. 7, right path). This work demonstrates the existence of an alternative targeting route mediated by SecA for cotranslational targeting to SecYEG sites and integration into the membrane (Fig. 7, middle path). The complete repertoire of substrate proteins using this targeting route remains to be defined. Nevertheless, together with the finding of other substrates that exhibit distinct requirements for alternative translocases (Samuelson et al., 2000; van der Laan et al., 2004), our results add to the diversity of protein-targeting mechanisms in bacteria.

SecA is an essential ATPase in bacteria known to drive the posttranslational translocation of secretory and outer membrane proteins across the SecYEG translocation machinery. The recent findings that SecA also binds ribosomes near the nascent polypeptide exit site (Huber et al., 2011; Singh et al., 2014) suggest additional roles for this protein, but the function of the SecA–ribosome interaction has been unclear. The previous model, in which nascent proteins contact SecA during translation and then engage SecB for membrane delivery after they are released from the ribosome (Huber et al., 2011), regresses to a largely posttranslational mechanism of targeting. The results in this study demonstrate a new possibility: SecA can specifically recognize and mediate the targeting/translocation of some inner membrane proteins in a strictly cotranslational manner. Although the interactions of SecA with nascent periplasmic and outer membrane proteins have been previously characterized and are known to facilitate translocation (Karamyshev and Johnson, 2005; Huber et al., 2011, 2016), the interaction and activity of SecA on the RodZ nascent chain observed in this study is the first example in which the cotranslational mode of SecA action is mechanistically obligatory for the proper biogenesis of the substrate protein. Thus, this work provides a potential mechanism by which the SecA–ribosome interaction plays an essential role in nascent protein biogenesis. Additional mechanistic roles for the SecA–ribosome interaction include providing an early chaperone for nascent polypeptides or facilitating the translocation of large periplasmic loops for proteins still bound to the ribosome; these possibilities remain to be explored.

Nascent RodZ was shown to bind SRP in ribosome profiling experiments (Schiibich et al., 2016). This is consistent with our observation in this study that RodZ still binds SRP with a $K_v$ value of 24 nM in the presence of physiological concentrations of TF and SecA (Fig. 6 C). Indeed, SRP altered the FRET value of the RNC–SecA complex, and the weakening effect of SRP on RNC–SecA binding saturated at SRP concentrations above 50 nM (Fig. S1 C). These observations argue against a model in which the binding of SRP and SecA to RNC$_{RodZ}$ is mutually exclusive and instead are more consistent with a model in which these two factors allosterically modulate the affinity and conformation of one another at the ribosome exit site (see
Figure 6. The NTE and early periplasmic region of RodZ together dictate the selection of a membrane protein into the SecA versus SRP pathway. (A) Scheme of the sequence elements of the substrate variants tested in this figure. Detailed sequences are in Table S1. (B and C) Summary of the $K_d$ values of RNCs bearing different nascent chains for binding to SecA (B) or SRP (C) derived from the equilibrium titrations in Fig. S4. All titrations contained 20 nM RNCs and 2 µM TF, 400 nM SRP, or 2 µM SecA where indicated. (D and E) In vitro translocation assays of WT RodZ or mutant RodZ$^{\text{NTE}}$ and their dependence on SecA (D) or SRP (E). (F and G) In vitro translocation assays of WT FtsQ and mutants RodZNTE-FtsQ and RodZNTE-peri-FtsQ. The dependence of the reaction on SecA was shown in F, and the dependence on SRP was shown in G. The reactions in D and F contained 3.8 µM TF, 400 nM Ffh, 1 µM FtsY, and indicated concentrations of SecA. The reactions in E and G contained 50 nM SecA, 3.8 µM TF, the indicated concentrations of SRP, and a fivefold excess of FtsY over SRP. Values represent mean ± SD; n = 2–3.
Arising as an effective strategy to ensure accurate nascent protein selection into the appropriate biogenesis pathway.

Figure 7. Diverse targeting pathways deliver nascent proteins to the Sec-YEG translocon at the inner membrane. Left path, proteins with weakly hydrophobic signal sequences are cotranslationally recognized by SRP and targeted to the SecYEG via the SecA-SR complex. Middle path, proteins harboring internal TMDs are cotranslationally recognized and targeted by SecA.

Materials and methods

Strains

The E. coli strains E0527 and WAM1211 have been described previously (de Gier et al., 1996; Or et al., 2005). To construct the strain KC623 harboring mutant L23 (KC6 ΔpL::kan pL23 F51A/E52A/E54A/E56A/E89A), DNA coding L23 mutations was cloned into pEK20 by Gibson assembly (Gibson et al., 2009) and transformed into the E. coli strain KC6 (A19 ΔendA metE ΔtonA ΔspeA ΔmnaA ΔdaaA ΔsdaB ΔgshA; Calhoun and Swartz, 2006). The genomic L23 in KC6 harboring pl23 F51A/E52A/E54A/E56A/E89A was then knock out by λ-red recombination (Datsenko and Wanner, 2000).

Protein expression and purification

N-terminally His6-tagged SecA (WT and mutant) was cloned in pET28a and expressed in BL21 (DE3) cells. Expression was induced by 0.5 mM IPTG at OD600 = 0.5 and 30°C for 4 h. Cells were lysed by FRENCH PRESS (Thermo Fisher Scientific) in SecA500 buffer (20 mM Hepes, pH 8.0, 2 mM EDTA, 2 mM DTT, 250 mM NaCl). Ffh was further purified by a Superose 12 gel filtration column (GE Healthcare) in Ffh buffer 2 (20 mM Hepes, pH 7.5, 200 mM KCl, 4 mM MgCl2, and 4 mM β-mercaptoethanol [BME]) containing 10 mM imidazole and cOmplete protease inhibitor cocktail (Roche). Clarified lysate was loaded onto Ni-NTA resin and washed with SecA500 buffer. Protein was eluted with SecA500 buffer containing 250 mM imidazole. The His6 tag was removed by tobacco etch virus protease digestion in SecA200 buffer (20 mM Hepes, pH 7.5, 200 mM KCl, 4 mM MgCl2, 10 mM imidazole, and 4 mM BME) at 4°C overnight and reloaded onto Ni-NTA. Flowthrough was collected, exchanged into SecA50 buffer (20 mM Tris-Cl, pH 8.0, 50 mM KCl, 4 mM MgCl2, and 2 mM DTT), and then further purified on MonoQ 10/100 GL (GE Healthcare) using a linear gradient of 50–1,000 mM KCl.

Ffh was expressed in pET3a vector with an E. coli BL21(DE3) plLyS strain (Peluso et al., 2000). At OD600 = 0.8, Ffh was induced by 1 mM IPTG at 37°C for 4 h. Cells were lysed in Ffh buffer 1 (20 mM Hepes, pH 8.0, 2 mM EDTA, 2 mM DTT, 250 mM NaCl, and 1 mM PMSF) by sonication. Clarified lysate was loaded onto an SP Sephrose fast flow column (GE Healthcare) equilibrated in Ffh buffer 1. Protein was eluted using a linear gradient of 250–1,000 mM NaCl. Ffh was further purified by a Superose 12 gel filtration column (GE Healthcare) in Ffh buffer 2 (20 mM Hepes, pH 8.0, 2 mM EDTA, 2 mM DTT, and 250 mM NaCl).
C-terminal His_{6}-tagged FtsY was cloned in pET9a vector and expressed in E. coli BL21(DE3) pLysS strain (Jagath et al., 2000). At $OD_{600} = 0.6$, FtsY was induced by 0.5 mM IPTG at 37°C for 5 h. Cells were lysed in FtsY buffer 1 (20 mM Heps, pH 7.5, 2 mM EDTA, 150 mM NaCl, 0.01% [wt/vol] nikkol, 2 mM DTT, and 1 mM PMSF) by sonication. Lysate was clarified in Ti 45 rotor (Beckman Coulter) at 38,000 rpm for 45 min and loaded onto Q Sepharose Fast Flow column (GE Healthcare) equilibrated in FtsY buffer 1 and bound protein was eluted by a linear gradient of 150–500 mM NaCl. FtsY was further purified by a Superose 12 gel filtration column in FtsY buffer 2 (20 mM Heps, pH 8.0, 2 mM EDTA, 2 mM DTT, and 250 mM NaCl). Pooled fractions were dialyzed against FtsY buffer 3 (20 mM Heps, pH 7.5, and 150 mM KCl) and then loaded onto Ni-NTA equilibrated in buffer 3. Bound protein was washed with FtsY buffer 4 (20 mM Heps, pH 7.5, 1 M KCl, and 10 mM imidazole) and eluted with FtsY buffer 5 (20 mM Heps, pH 7.5, 150 mM KCl, and 200 mM imidazole). Protein was further dialyzed against FtsY buffer 5 (50 mM Tris-HCl, pH 7.4, 1 mM EDTA, and 2 mM DTT) and loaded onto MonoQ (10/100 GL) equilibrated in FtsY buffer 5. FtsY was eluted by a linear gradient of 150–1,000 mM NaCl.

TF was cloned in pH6 vector and expressed in E. coli DH5α strain transformed with pZA4 (Ariosa et al., 2015). Cells were grown at 30°C to $OD_{600} = 0.6$, induced by 0.5 mM IPTG for 3 h, and then lysed in TF buffer 1 (50 mM Tris-HCl, pH 7.5, 20 mM imidazole, 200 mM NaCl, 1 mM EDTA, 4 mM BME, and 1 mM PMSF) by FRENCH PRESS. Clarified lysate was loaded onto Ni-NTA equilibrated in TF buffer 1. TF was eluted with TF buffer 2 (50 mM Tris-HCl, pH 7.5, 500 mM imidazole, 200 mM NaCl, 1 mM BME, and 1 mM PMSF) and dialyzed against TF buffer 3 (50 mM Tris-HCl, pH 7.5, 50 mM NaCl, 1 mM EDTA, and 1 mM DTT). Protein was further purified on MonoQ 10/100 GL (GE Healthcare) using a linear gradient of 100–1,000 mM NaCl.

pHKSB366 encoding SecB was a gift from A. Karamyshov (Texas Tech University, Lubbock, TX; Fekkes et al., 1998). SecB was expressed in BL21(DE3) using 1 mM IPTG at $OD_{600} = 1.0$ at 37°C for 2 h. Cells were lysed by sonication in SecB buffer 1 (50 mM potassium phosphate, pH 7.5, and 300 mM NaCl) containing 20 mM imidazole. Clarified lysate was precipitated with 50% ammonium sulfate and centrifuged at 10,000 g for 10 min. The pellet was resuspended in SecB buffer 1 and loaded onto Ni-NTA equilibrated with SecB buffer 1. SecB was eluted with SecB buffer 1 containing 500 mM imidazole followed by dialysis in 50 mM Tris, pH 7.5. After ultracentrifugation in TLA 100.3 (Beckman Coulter) at 60,000 g for 1 h, the supernatant was loaded onto MonoQ equilibrated in SecB buffer 2 (50 mM Tris-HCl, pH 7.5, and 30 mM NaCl) and eluted with a linear gradient of 30–1,000 mM NaCl. The protein was desalted in SecB buffer 2.

SUMO and SUMO fusions to the periplasmic segments of RodZ or FtsQ were expressed using a pET28 vector encoding N-terminal His_{6}-tagged full-length SUMO family protein SMT3 from Saccharomyces cerevisiae fused to RodZ residues 134–160 or FtsQ residues 50–74 where applicable. Proteins were expressed in BL21(DE3) using 0.5 mM IPTG at $OD_{600} = 0.5$ and 37°C for 3 h. Cell was lysed by sonication in SUMO buffer 1 (20 mM Heps, pH 7.5, 300 mM NaCl, and 4 mM BME) containing 20 mM imidazole and Complete protease inhibitor cocktail. Clarified lysate was loaded onto Ni-NTA resin and washed with SUMO buffer 1. Protein was eluted with SUMO buffer 1 containing 250 mM imidazole. Proteins were dialyzed against SUMO buffer 2 (20 mM Heps, pH 7.5, 300 mM NaCl, 10% glycerol, and 2 mM TCEP) at 4°C and stored at −80°C.

**RNC preparation**

Cm-labeled RNCs were generated by IVT in S30 extract supplemented with Cm (Bachem), tRNA Cm, and Cm tRNA synthetase as described previously (Schaffitzel et al., 2006). In brief, pUC19 plasmids (0.06 mg/ml) containing T7 promoter followed by nascent chain coding sequence and SecM arrest sequence (Table S1) were transcribed and translated in 5–10 ml reaction mixture containing 12 mM magnesium glutamate, 10 mM ammonium glutamate, 175 mM potassium glutamate, 1.2 mM ATP, 0.86 mM GTP, 0.86 mM CTP, 0.86 mM UTP, 34 µg/ml folic acid, 0.17 mg/ml E. coli tRNA (Roche), amino acid mix (2 mM each), 33 mM phosphoenolpyruvate, 0.33 mM β-nicotinamide adenine dinucleotide, 0.26 mM CoA, 2.7 mM sodium oxalate, 1.5 mM spermidine, 1 mM putrescine, 4 µM anti–ssr1 oligonucleotide, 12 µM RFI aptamer (Saragoi et al., 2011), 28% (vol/vol) S30 extract, 12 µM coumarine synthetase D286R (Wang et al., 2006), 2 µM T7 RNA polymerase, and 75 µM Cm (Bachem), pH 7.8, at 30°C for 1.5 h. Reaction samples were loaded onto a StrepTactin column (IBA) equilibrated in solution 1 (50 mM Heps, pH 7.5, 100 mM KCl, and 100 mM Mg(OAc)_{2}) and washed with solution 1 containing 500 mM KCl. RNCs were eluted using solution 1 containing 1.5 mg/ml t-desthiobiotin (Sigma-Aldrich). Strep tag was removed by thrombin (Roche). RNCs were sedimented in Ti 70 rotor (Beckman Coulter) at 42,000 rpm for 3.5 h and resuspended in SRP buffer (50 mM Heps, pH 7.5, 150 mM KCl, 10 mM Mg(OAc)$_2$, and 2 mM DTT) at 4°C overnight. To prepare RNCs harboring mutant L23(F51A/E52A/E54A/E56A/E89A), S30 extract was prepared from the strain KC623 harboring L23 mutant (KC6 ΔgprF::kan pL23(F51A/E52A/E54A/E56A/E89A); see the Strains section for strain construction).

**RNaseA/EDTA treatment of RNCs**

To release nascent chains from the ribosome, RNCs were incubated with 20 mM EDTA, pH 8.0, and 50 µg/ml RNase A at 37°C for 30 min (Ziehr et al., 2010). To verify the effectiveness of this treatment, RNCs before and after the treatment were sedimented in a TLA 100 (Beckman Coulter) rotor at 100,000 g for 2.5 h. The pellet was resuspended with SDS loading buffer at equal volume as the supernatant; both pellet and supernatant fractions were subject to SDS-PAGE analysis.

**Fluorescent labeling**

The single cysteine mutant Ffh (C406S/D421C) and the single cysteine mutant SecA(C98S/S12C) were purified as described in the Protein expression and purification section. They were reduced with 2 mM DTT at 4°C for 30 min followed by dialysis in labeling buffer (20 mM Heps, pH 7.0, 300 mM KCl, 10% glycerol, and 2 mM TCEP) to remove DTT. 70 µM Ffh (C406S/D421C) was mixed with a 30-fold excess of BDP maleimide, and 40 µM SecA (C98S/S12C) was mixed with a 20-fold excess of BDP maleimide on a rotary shaker at 4°C for 4 h. After quenching with 10 mM DTT, free dye was removed by chromatography on Sephadex G-25 column (Sigma-Aldrich) in SRP buffer (50 mM Heps, pH 7.5, 150 mM KCl, 10 mM Mg(OAc)$_2$, and 2 mM DTT) and 10 mM EDTA treatment of RNCs

**Fluorescence measurements**

All proteins were ultracentrifuged in TLA 100 (Beckman Coulter) at 100,000 g for 1 h before fluorescence measurements. Fluorescence experiments were performed as described previously (Zhang et al., 2010; Ariosa et al., 2015) at room temperature in assay buffer (50 mM Heps, pH 7.5, 150 mM KCl, 10 mM Mg(OAc)$_2$, 2 mM DTT, and 0.1 mg/ml BSA). Experiments were performed on Fluorolog-3 (HORIBA) using 360-nm excitation wavelength (slit, 4 nm) and 455-nm emission wavelength (slit, 10 nm) for equilibrium titrations. Equilibrium titrations were performed using 20 nM Cm-labeled RNC, indicated...
concentrations of cytosolic competitors where applicable, and SecA or Ffh as the titrant. The observed FRET value at individual titrant concentrations (FRET_{obd}) were calculated from Eq. 1,

\[ FRET_{obd} = 1 - \frac{D_A}{D_0}, \]

in which \( D_0 \) is the donor fluorescence signal in the absence of the FRET acceptor, and \( D_A \) is the donor fluorescence signal in the presence of the acceptor-labeled titrant.

The concentration dependence of FRET_{obd} in a titration curve was fit to Eq. 2 (Cooper, 2004),

\[ FRET_{obd} = FRET_{max} \times \frac{[RNC] + [titrant] + K_d \sqrt{([RNC] + [titrant] + K_d)^2 - 4 \times [RNC] \times [titrant]}}{2 \times [RNC]}, \]

in which \([RNC], [titrant]\), and FRET are input values, FRET_{max} is the FRET value at saturating titrant concentration, and \( K_d \) is the dissociation constant of the complex of interest.

To facilitate comparison of complexes with different \( K_d \) values, FRET_{obd} was further divided by the FRET_{max} values obtained from fitting the data to Eq. 2 to generate normalized titration curves. These curves are described by Eq. 3:

\[ \text{Normalized } \Delta F = 1 \times \frac{[RNC] + [titrant] + K_d \sqrt{([RNC] + [titrant] + K_d)^2 - 4 \times [RNC] \times [titrant]}}{2 \times [RNC]}, \]

To measure the binding of the SUMO-RodZPeri fusion protein to SecA, 50 nM SecA^{BDP} was preincubated with 20 nM Cm-labeled RNC_{RodZ}. Increasing concentrations of SUMO-RodZ(peri) were added to SecA, 50 nM SecA^{BDP} was preincubated with 20 nM Cm-labeled RNC_{RodZ} (\( F_{obd} \)) were recorded. The data were fit to Eq. 8, derived by rearranging Eq. 7, to describe the double reciprocal plot.

\[ F_{obd} = F_0 + m \times \frac{-[SU] - 31 \times K_i + \sqrt{[SU]^2 + 142 + [SU] \times K_i + 1.041 \times K_i^2}}{2 \times K_i^2}. \]

In Eq 8, [SU] is the concentration of SUMO variant, \( K_i \) is the inhibition constant of the competitors for SecA, \( F_0 \) is the initial fluorescence intensity of Cm-labeled RNC_{RodZ} in the SecA^{BDP}...RNC_{Cm} complex, and \( m \) is the contribution to fluorescence intensity per nanomole of RNC_{Cm}.

**In vivo translocation assay of NTS-TrxA fusions**

pEK20 plasmids coding NTS-TrxA-myc fusion proteins were transformed into *E. coli* strains EO527 and WAM121, in which the expression of SecA and Ffh, respectively, were under control of the arabinose promoter (de Gier et al., 1996; Or et al., 2005). To deplete Ffh, WAM121 cells were grown to OD_{600} = 0.5 in LB supplemented with 0.02% (wt/vol) l-arabinose, washed twice with LB supplemented with 0.4% (wt/vol) d-glucose, and subcultured in LB supplemented with 0.4% (wt/vol) d-glucose. Ffh level was reduced to <5% after 3 h of media shift. SecA depletion in EO527 was performed similarly to Ffh depletion except that the subculture was grown for 5 h to deplete SecA. At OD_{600} = 0.4–0.6, NTS-TrxA-myc expression was induced by addition of IPTG (5 μM for RodZ and RodZNTE-FtsQ, 50 μM for all other constructs to achieve similar expression levels; Fig. S2 B) for 30 min at 37°C. Cells were harvested and resuspended in cold TrxA buffer 1 (0.1 M Tris-HCl, pH 8.0, and 20% sucrose). 0.5 mM EDTA, pH 8.0 and 50 μg/ml lysozyme were added, and the suspension was incubated at room temperature for 15 min. 20 mM MgSO_4 was added to stabilize spheroplasts. Spheroplasts were separated from the periplasmic fraction by centrifugation at 3,140 g for 10 min. For the protease K protection assay, spheroplasts were resuspended in cold TrxA buffer 2 (0.1 M Tris-HCl, pH 8.0, 20% sucrose, and 20 mM MgSO_4) and incubated with or without 0.5 mg/ml protease K on ice for 1 h. Reactions were stopped by addition of 5 mM PMSF. To further separate the cytosol from the membrane fraction, spheroplasts were resuspended in TrxA buffer 3 (50 mM Tris-HCl, pH 8.0, 150 mM NaCl, 1 mM EDTA, and 1 mM PMSF), lysed by one freeze-thaw cycle in liquid nitrogen, and clarified in TLA120.1 rotor at 63,000 rpm for 1 h. The supernatant was the cytosolic fraction, and the membrane pellet was resuspended with TrxA buffer 4 (20 mM Tris-HCl, pH 8.0, 5 mM EDTA, and 0.5% SDS). The translocation efficiencies for secretory proteins were calculated from the ratio of the secreted fraction to total protein amount. The translocation efficiencies for membrane proteins were calculated from the ratio of protein intensity after/before proteinase K digestion.

**Western blot**

Rabbit anti-SecA antibody was a gift from T.A. Rapoport (Harvard Medical School, Boston, MA). Rabbit anti-Ffh antibody was a gift from P. Walter (University of California, San Francisco, San Francisco, CA). Rabbit anti-YidC antibody was a gift from R.E. Dalbey (Ohio State University, Columbus, OH). The following antibodies were commercially available: rabbit anti-TrxA antibody (T0803; Sigma-Aldrich), mouse anti-β-lactamase antibody (MA1-10712; Thermo Fisher Scientific), and rabbit anti–myc tag antibody (ab9106; Abcam). Primary antibodies were incubated with IRDye 800CW goat anti–rabbit IgG (925-32211; LI-COR Biosciences) or IRDye 800CW goat anti–mouse IgG (925-32210; LI-COR Biosciences) for detection. Protein band intensity was quantified by the Odyssey CLx imaging system (LI-COR Biosciences).

**Preparation of U-IMVs**

SecYEG was overexpressed in MRE600 by induction with 0.5 mM IPTG for 2 h. Cells were harvested in IMV buffer 1 (50 mM TEA-OAc, pH 7.5, 250 mM sucrose, 1 mM EDTA, 1 mM DTT, and 0.5 mM PMSF) and lysed at 8,000 psi by FRENCH PRESS. Unbroken cells were removed by centrifugation at 4,000 g for 10 min. Membranes were further pelleted in a Ti 70 rotor at 45,000 rpm for 2 h and resuspended in IMV buffer 1. The membrane suspension was layered onto a five-step sucrose gradient (0.8, 1.0, 1.2, 1.4, and 1.6 M sucrose in IMV buffer 1) and ultracentrifuged in SW32 (Beckman Coulter) at 24,000 rpm for 16 h. IMV fractions were collected from the lower one third
of the gradient as described previously (Müller and Blobel, 1984a). To make U-IMVs, four volumes of IMV buffer 2 (50 mM TEA-OAc, pH 7.5, 250 mM sucrose, 1 M KOAc, and 7.5 M urea) were added to IMVs. The mixture was incubated on ice for 1 h, after which the urea concentration was adjusted to 3 M before pelleting through a sucrose cushion (50 mM TEA-OAc, pH 7.5, 750 mM sucrose, 1 M KOAc, and 1 mM DTG) in TLA100.3 at 60,000 rpm for 2 h. The pellet was resuspended in IMV buffer 3 (50 mM TEA-OAc, pH 7.5, 250 mM sucrose, and 1 mM DTG; Müller and Blobel, 1984b; Helde et al., 1997).

In vitro translocation assay in PURE system
Translation was performed at 30°C using a PURExpress in vitro protein synthesis kit (New England Biolabs, Inc.) supplemented with [35S]methionine (1.5 mM/mI; PerkinElmer) and indicated concentrations of cytosolic factors (SecA, SecB, Ffh, FtsY, or TF). Unless otherwise indicated, 0.5 mg/ml U-IMVs was added 5 min after initiation of translation. The reaction was continued for 85 min at 30°C, after which it was split equally into two samples, one of which was digested with 0.5 mg/ml protease K for 30 min at 25°C. Digestion was stopped by addition of 5 mM PMSF, after which the sample was incubated on ice for 10 min. Samples with and without protease K treatment were analyzed by SDS-PAGE and autoradiography. The insertion efficiency was calculated from the ratio of the intensity of substrate protein bands after and before protease K treatment. The loss of methionine or methionines after protease K digestion was corrected before calculation of insertion efficiency.

ProOmpA translocation in wheat germ lysate
ProOmpA mRNA was in vitro transcribed and purified as described previously (Behrmann et al., 1998). ProOmpA was translated using wheat germ extract (Promega) in the presence of [35S]methionine (1.5 mM/ml) at 26°C for 30 min, followed by incubation with U-IMVs at 37°C for 15 min in the presence of 10 mM phosphocreatine, 0.05 mg/ml creatine kinase, 4 mM Mg(OAc)2, 2 mM ATP, 0.5 mg/ml BSA, 10 mM DTG, and the indicated concentrations of SecA. Samples were digested with 0.1 mg/ml protease K on ice for 15 min. Digestion was stopped by addition of 5 mM PMSF. All samples were precipitated by TCA and analyzed by SDS-PAGE and autoradiography.

Online supplemental material
Fig. S1 shows the controls for titration experiments and raw FRET titrations before normalization. Fig. S2 shows the SRP and SecA dependence of the targeting and translocation of TrxA fusion constructs in vivo. Fig. S3 shows replicates for the SecA/SecY dependence of translocation reactions across U-IMVs in vitro. Fig. S4 shows the equilibrium titration curves to measure the binding of SecA and SRP to RNCs bearing the nascent chains of RodZ, RodZ[NTE], FtsX, RodZNTE-FtsQ, and RodZNTE-peri-FtsQ. Table S1 summarizes the sequence of various substrates used in RNC binding and in vivo translocation assays.

Acknowledgments
We thank Stephen H. White and Eric Lindner for discussions and members of the Shan group for comments on the manuscript.

This work was supported by National Institutes of Health grant GM107368A and the Gordon and Betty Moore Foundation through grant GBMF2939 to S.-o. Shan. The authors declare no competing financial interests.

Author contributions: S. Wang designed and performed most of the experiments. C.-I. Yang assisted in measuring the binding affinity of RNCs to SecA and SRP. S. Wang and S.-o. Shan wrote the paper. S.-o. Shan conceived the project. All authors reviewed the manuscript.
